## HOW TO PROGRAM

NINTH EDITION

PAUL DEITEL  
HARVEY DEITEL

## DEITEL® HOW TO PROGRAM SERIES Cover Theme

The cover theme for the DEITEL® HOW TO PROGRAM SERIES emphasizes social consciousness issues such as going green, clean energy, recycling, sustainability and more. Within the text, in addition to conventional programming exercises, we've included our Making a Difference exercise set to raise awareness of issues such as global warming, population growth, affordable healthcare, accessibility, privacy of electronic records and more. In this book, you'll use Java to program applications that relate to these issues. We hope that what you learn in *Java How to Program, 9/e* will help you to make a difference.

### Night at the Niagara Falls—Ontario and New York

The Niagara Falls waterfalls straddle the border between Ontario, Canada and upstate New York in the United States. Horseshoe Falls is located on the Canadian side, and American Falls and Bridal Veil Falls are on the U.S. side.

The Niagara Falls are an awe-inspiring, world-class tourist attraction, and a significant source of hydroelectric power. On average, nearly four million cubic feet of water falls over the crest line each minute. The U.S. and Canada harness the natural energy from Niagara Falls to generate clean, inexpensive electricity. The first hydroelectric generating station on the Niagara River was built in 1881. Its electricity powered local mills and street lights. The Niagara Redevelopment Act, passed by the U.S. Congress in 1957, gave the New York Power Authority the right to develop the U.S. Niagara River hydroelectric power plants. The Niagara Falls hydroelectric project began operating in 1961. Up to 375,000 gallons of water per second is diverted from the river through conduits to the power plants. The water spins turbines that power generators that convert the mechanical energy into electrical energy. Today, the project generates 2.4 million kilowatts, which can power 24 million 100-watt light bulbs simultaneously. For further information visit:

### About Deitel & Associates, Inc.

Deitel & Associates, Inc., is an internationally recognized authoring and corporate training organization. The company offers instructor-led courses delivered at client sites worldwide on programming languages and other software topics such as Java™, C#®, Visual Basic®, Visual C++®, C++, C, Objective-C®, XML®, Python®, JavaScript, object technology, Internet and web programming, and Android and iPhone app development. The company's clients include many of the world's largest companies, as well as government agencies, branches of the military and academic institutions. To learn more about Deitel Pearson Higher Education publications and Dive Into® Series corporate training, e-mail [deitel@deitel.com](mailto:deitel@deitel.com) or visit [www.deitel.com/training/](http://www.deitel.com/training/). Follow Deitel on Facebook® at [www.deitel.com/deitelFan/](http://www.deitel.com/deitelFan/) and on Twitter® @deitel.

**Preface** **xxiii**

**Before You Begin** **xxxiii**

**1 Introduction to Computers and Java** **1**

1.1	Introduction	2
1.2	Computers: Hardware and Software	5
1.3	Data Hierarchy	6
1.4	Computer Organization	8
1.5	Machine Languages, Assembly Languages and High-Level Languages	10
1.6	Introduction to Object Technology	11
1.7	Operating Systems	13
1.8	Programming Languages	16
1.9	Java and a Typical Java Development Environment	18
1.10	Test-Driving a Java Application	22
1.11	Web 2.0: Going Social	26
1.12	Software Technologies	29
1.13	Keeping Up-to-Date with Information Technologies	31
1.14	Wrap-Up	32

**2 Introduction to Java Applications** **37**

2.1	Introduction	38
2.2	Your First Program in Java: Printing a Line of Text	38
2.3	Modifying Your First Java Program	44
2.4	Displaying Text with <code>printf</code>	46
2.5	Another Application: Adding Integers	47
2.6	Memory Concepts	52

2.7	Arithmetic	53
2.8	Decision Making: Equality and Relational Operators	56
2.9	Wrap-Up	60

### **3 Introduction to Classes, Objects, Methods and Strings 71**

3.1	Introduction	72
3.2	Declaring a Class with a Method and Instantiating an Object of a Class	72
3.3	Declaring a Method with a Parameter	76
3.4	Instance Variables, <i>set</i> Methods and <i>get</i> Methods	79
3.5	Primitive Types vs. Reference Types	84
3.6	Initializing Objects with Constructors	85
3.7	Floating-Point Numbers and Type <code>double</code>	88
3.8	(Optional) GUI and Graphics Case Study: Using Dialog Boxes	92
3.9	Wrap-Up	95

### **4 Control Statements: Part I 102**

4.1	Introduction	103
4.2	Algorithms	103
4.3	Pseudocode	104
4.4	Control Structures	104
4.5	<code>if</code> Single-Selection Statement	107
4.6	<code>if...else</code> Double-Selection Statement	107
4.7	<code>while</code> Repetition Statement	112
4.8	Formulating Algorithms: Counter-Controlled Repetition	113
4.9	Formulating Algorithms: Sentinel-Controlled Repetition	118
4.10	Formulating Algorithms: Nested Control Statements	125
4.11	Compound Assignment Operators	130
4.12	Increment and Decrement Operators	130
4.13	Primitive Types	134
4.14	(Optional) GUI and Graphics Case Study: Creating Simple Drawings	134
4.15	Wrap-Up	138

### **5 Control Statements: Part 2 151**

5.1	Introduction	152
5.2	Essentials of Counter-Controlled Repetition	152
5.3	<code>for</code> Repetition Statement	154
5.4	Examples Using the <code>for</code> Statement	158
5.5	<code>do...while</code> Repetition Statement	162
5.6	<code>switch</code> Multiple-Selection Statement	164
5.7	<code>break</code> and <code>continue</code> Statements	172
5.8	Logical Operators	173
5.9	Structured Programming Summary	179

5.10	(Optional) GUI and Graphics Case Study: Drawing Rectangles and Ovals	184
5.11	Wrap-Up	187

## **6 Methods: A Deeper Look** **197**

6.1	Introduction	198
6.2	Program Modules in Java	198
6.3	static Methods, static Fields and Class Math	200
6.4	Declaring Methods with Multiple Parameters	202
6.5	Notes on Declaring and Using Methods	205
6.6	Method-Call Stack and Activation Records	206
6.7	Argument Promotion and Casting	207
6.8	Java API Packages	208
6.9	Case Study: Random-Number Generation	210
6.9.1	Generalized Scaling and Shifting of Random Numbers	214
6.9.2	Random-Number Repeatability for Testing and Debugging	214
6.10	Case Study: A Game of Chance; Introducing Enumerations	215
6.11	Scope of Declarations	219
6.12	Method Overloading	222
6.13	(Optional) GUI and Graphics Case Study: Colors and Filled Shapes	224
6.14	Wrap-Up	227

## **7 Arrays and ArrayLists** **240**

7.1	Introduction	241
7.2	Arrays	242
7.3	Declaring and Creating Arrays	243
7.4	Examples Using Arrays	244
7.5	Case Study: Card Shuffling and Dealing Simulation	254
7.6	Enhanced for Statement	258
7.7	Passing Arrays to Methods	259
7.8	Case Study: Class GradeBook Using an Array to Store Grades	262
7.9	Multidimensional Arrays	268
7.10	Case Study: Class GradeBook Using a Two-Dimensional Array	271
7.11	Variable-Length Argument Lists	278
7.12	Using Command-Line Arguments	279
7.13	Class Arrays	281
7.14	Introduction to Collections and Class ArrayList	284
7.15	(Optional) GUI and Graphics Case Study: Drawing Arcs	286
7.16	Wrap-Up	289

## **8 Classes and Objects: A Deeper Look** **311**

8.1	Introduction	312
8.2	Time Class Case Study	312
8.3	Controlling Access to Members	316
8.4	Referring to the Current Object's Members with the this Reference	317
8.5	Time Class Case Study: Overloaded Constructors	320

8.6	Default and No-Argument Constructors	326
8.7	Notes on <i>Set</i> and <i>Get</i> Methods	326
8.8	Composition	328
8.9	Enumerations	331
8.10	Garbage Collection and Method <code>finalize</code>	333
8.11	<code>static</code> Class Members	334
8.12	<code>static</code> Import	338
8.13	<code>final</code> Instance Variables	339
8.14	Time Class Case Study: Creating Packages	340
8.15	Package Access	345
8.16	(Optional) GUI and Graphics Case Study: Using Objects with Graphics	347
8.17	Wrap-Up	351

## **9 Object-Oriented Programming: Inheritance 359**

9.1	Introduction	360
9.2	Superclasses and Subclasses	361
9.3	<code>protected</code> Members	363
9.4	Relationship between Superclasses and Subclasses	364
9.4.1	Creating and Using a <code>CommissionEmployee</code> Class	364
9.4.2	Creating and Using a <code>BasePlusCommissionEmployee</code> Class	370
9.4.3	Creating a <code>CommissionEmployee–BasePlusCommissionEmployee</code> Inheritance Hierarchy	375
9.4.4	<code>CommissionEmployee–BasePlusCommissionEmployee</code> Inheritance Hierarchy Using <code>protected</code> Instance Variables	377
9.4.5	<code>CommissionEmployee–BasePlusCommissionEmployee</code> Inheritance Hierarchy Using <code>private</code> Instance Variables	380
9.5	Constructors in Subclasses	385
9.6	Software Engineering with Inheritance	386
9.7	Class Object	387
9.8	(Optional) GUI and Graphics Case Study: Displaying Text and Images Using Labels	388
9.9	Wrap-Up	391

## **10 Object-Oriented Programming: Polymorphism 394**

10.1	Introduction	395
10.2	Polymorphism Examples	397
10.3	Demonstrating Polymorphic Behavior	398
10.4	Abstract Classes and Methods	400
10.5	Case Study: Payroll System Using Polymorphism	403
10.5.1	Abstract Superclass <code>Employee</code>	404
10.5.2	Concrete Subclass <code>SalariedEmployee</code>	407
10.5.3	Concrete Subclass <code>HourlyEmployee</code>	408
10.5.4	Concrete Subclass <code>CommissionEmployee</code>	410
10.5.5	Indirect Concrete Subclass <code>BasePlusCommissionEmployee</code>	412
10.5.6	Polymorphic Processing, Operator <code>instanceof</code> and Downcasting	413

10.5.7	Summary of the Allowed Assignments Between Superclass and Subclass Variables	418
10.6	final Methods and Classes	418
10.7	Case Study: Creating and Using Interfaces	419
10.7.1	Developing a Payable Hierarchy	421
10.7.2	Interface Payable	422
10.7.3	Class Invoice	422
10.7.4	Modifying Class Employee to Implement Interface Payable	425
10.7.5	Modifying Class SalariedEmployee for Use in the Payable Hierarchy	427
10.7.6	Using Interface Payable to Process Invoices and Employees Polymorphically	428
10.7.7	Common Interfaces of the Java API	430
10.8	(Optional) GUI and Graphics Case Study: Drawing with Polymorphism	431
10.9	Wrap-Up	433

## **11 Exception Handling: A Deeper Look** **438**

11.1	Introduction	439
11.2	Example: Divide by Zero without Exception Handling	439
11.3	Example: Handling ArithmeticExceptions and InputMismatchExceptions	442
11.4	When to Use Exception Handling	447
11.5	Java Exception Hierarchy	447
11.6	finally Block	450
11.7	Stack Unwinding and Obtaining Information from an Exception Object	454
11.8	Chained Exceptions	457
11.9	Declaring New Exception Types	459
11.10	Preconditions and Postconditions	460
11.11	Assertions	461
11.12	(New in Java SE 7) Multi-catch: Handling Multiple Exceptions in One catch	462
11.13	(New in Java SE 7) try-with-Resources: Automatic Resource Deallocation	463
11.14	Wrap-Up	463

## **12 ATM Case Study, Part I: Object-Oriented Design with the UML** **469**

12.1	Case Study Introduction	470
12.2	Examining the Requirements Document	470
12.3	Identifying the Classes in a Requirements Document	478
12.4	Identifying Class Attributes	484
12.5	Identifying Objects' States and Activities	489
12.6	Identifying Class Operations	493
12.7	Indicating Collaboration Among Objects	499
12.8	Wrap-Up	506

<b>13</b>	<b>ATM Case Study Part 2: Implementing an Object-Oriented Design</b>	<b>510</b>
13.1	Introduction	511
13.2	Starting to Program the Classes of the ATM System	511
13.3	Incorporating Inheritance and Polymorphism into the ATM System	516
13.4	ATM Case Study Implementation	522
13.4.1	Class ATM	523
13.4.2	Class Screen	528
13.4.3	Class Keypad	529
13.4.4	Class CashDispenser	530
13.4.5	Class DepositSlot	531
13.4.6	Class Account	532
13.4.7	Class BankDatabase	534
13.4.8	Class Transaction	537
13.4.9	Class BalanceInquiry	538
13.4.10	Class Withdrawal	539
13.4.11	Class Deposit	543
13.4.12	Class ATMCaseStudy	546
13.5	Wrap-Up	546
<b>14</b>	<b>GUI Components: Part I</b>	<b>549</b>
14.1	Introduction	550
14.2	Java's New Nimbus Look-and-Feel	551
14.3	Simple GUI-Based Input/Output with JOptionPane	552
14.4	Overview of Swing Components	555
14.5	Displaying Text and Images in a Window	557
14.6	Text Fields and an Introduction to Event Handling with Nested Classes	561
14.7	Common GUI Event Types and Listener Interfaces	567
14.8	How Event Handling Works	569
14.9	JButton	571
14.10	Buttons That Maintain State	574
14.10.1	JCheckBox	574
14.10.2	JRadioButton	577
14.11	JComboBox; Using an Anonymous Inner Class for Event Handling	580
14.12	JList	584
14.13	Multiple-Selection Lists	586
14.14	Mouse Event Handling	589
14.15	Adapter Classes	594
14.16	JPanel Subclass for Drawing with the Mouse	597
14.17	Key Event Handling	601
14.18	Introduction to Layout Managers	604
14.18.1	FlowLayout	605
14.18.2	BorderLayout	608
14.18.3	GridLayout	611
14.19	Using Panels to Manage More Complex Layouts	613

14.20	JTextArea	615
14.21	Wrap-Up	618

## **15 Graphics and Java 2D** **631**

15.1	Introduction	632
15.2	Graphics Contexts and Graphics Objects	634
15.3	Color Control	635
15.4	Manipulating Fonts	642
15.5	Drawing Lines, Rectangles and Ovals	647
15.6	Drawing Arcs	651
15.7	Drawing Polygons and Polylines	654
15.8	Java 2D API	657
15.9	Wrap-Up	664

## **16 Strings, Characters and Regular Expressions** **672**

16.1	Introduction	673
16.2	Fundamentals of Characters and Strings	673
16.3	Class <code>String</code>	674
16.3.1	String Constructors	674
16.3.2	String Methods <code>length</code> , <code>charAt</code> and <code>getChars</code>	675
16.3.3	Comparing Strings	676
16.3.4	Locating Characters and Substrings in Strings	681
16.3.5	Extracting Substrings from Strings	683
16.3.6	Concatenating Strings	684
16.3.7	Miscellaneous String Methods	684
16.3.8	String Method <code>valueOf</code>	686
16.4	Class <code>StringBuilder</code>	687
16.4.1	<code>StringBuilder</code> Constructors	688
16.4.2	<code>StringBuilder</code> Methods <code>length</code> , <code>capacity</code> , <code>setLength</code> and <code>ensureCapacity</code>	688
16.4.3	<code>StringBuilder</code> Methods <code>charAt</code> , <code>setCharAt</code> , <code>getChars</code> and <code>reverse</code>	690
16.4.4	<code>StringBuilder</code> append Methods	691
16.4.5	<code>StringBuilder</code> Insertion and Deletion Methods	693
16.5	Class <code>Character</code>	694
16.6	Tokenizing Strings	699
16.7	Regular Expressions, Class <code>Pattern</code> and Class <code>Matcher</code>	700
16.8	Wrap-Up	708

## **17 Files, Streams and Object Serialization** **719**

17.1	Introduction	720
17.2	Files and Streams	720
17.3	Class <code>File</code>	722
17.4	Sequential-Access Text Files	726
17.4.1	Creating a Sequential-Access Text File	726

17.4.2	Reading Data from a Sequential-Access Text File	733
17.4.3	Case Study: A Credit-Inquiry Program	736
17.4.4	Updating Sequential-Access Files	741
17.5	Object Serialization	742
17.5.1	Creating a Sequential-Access File Using Object Serialization	743
17.5.2	Reading and Deserializing Data from a Sequential-Access File	749
17.6	Additional <code>java.io</code> Classes	751
17.6.1	Interfaces and Classes for Byte-Based Input and Output	751
17.6.2	Interfaces and Classes for Character-Based Input and Output	753
17.7	Opening Files with <code>JFileChooser</code>	754
17.8	Wrap-Up	757

## **18 Recursion** **765**

18.1	Introduction	766
18.2	Recursion Concepts	767
18.3	Example Using Recursion: Factorials	768
18.4	Example Using Recursion: Fibonacci Series	771
18.5	Recursion and the Method-Call Stack	774
18.6	Recursion vs. Iteration	776
18.7	Towers of Hanoi	777
18.8	Fractals	779
18.9	Recursive Backtracking	790
18.10	Wrap-Up	790

## **19 Searching, Sorting and Big O** **798**

19.1	Introduction	799
19.2	Searching Algorithms	800
19.2.1	Linear Search	800
19.2.2	Binary Search	804
19.3	Sorting Algorithms	809
19.3.1	Selection Sort	810
19.3.2	Insertion Sort	814
19.3.3	Merge Sort	817
19.4	Wrap-Up	824

## **20 Generic Collections** **829**

20.1	Introduction	830
20.2	Collections Overview	830
20.3	Type-Wrapper Classes for Primitive Types	831
20.4	Autoboxing and Auto-Unboxing	832
20.5	Interface <code>Collection</code> and Class <code>Collections</code>	832
20.6	Lists	833
20.6.1	<code>ArrayList</code> and <code>Iterator</code>	834
20.6.2	<code>LinkedList</code>	836

20.7	Collections Methods	841
20.7.1	Method <code>sort</code>	842
20.7.2	Method <code>shuffle</code>	845
20.7.3	Methods <code>reverse</code> , <code>fill</code> , <code>copy</code> , <code>max</code> and <code>min</code>	847
20.7.4	Method <code>binarySearch</code>	849
20.7.5	Methods <code>addAll</code> , <code>frequency</code> and <code>disjoint</code>	851
20.8	Stack Class of Package <code>java.util</code>	853
20.9	Class <code>PriorityQueue</code> and Interface <code>Queue</code>	855
20.10	Sets	856
20.11	Maps	859
20.12	<code>Properties</code> Class	863
20.13	Synchronized Collections	866
20.14	Unmodifiable Collections	866
20.15	Abstract Implementations	867
20.16	Wrap-Up	867

## **21 Generic Classes and Methods** **873**

21.1	Introduction	874
21.2	Motivation for Generic Methods	874
21.3	Generic Methods: Implementation and Compile-Time Translation	877
21.4	Additional Compile-Time Translation Issues: Methods That Use a Type Parameter as the Return Type	880
21.5	Overloading Generic Methods	883
21.6	Generic Classes	883
21.7	Raw Types	891
21.8	Wildcards in Methods That Accept Type Parameters	895
21.9	Generics and Inheritance: Notes	899
21.10	Wrap-Up	900

## **22 Custom Generic Data Structures** **904**

22.1	Introduction	905
22.2	Self-Referential Classes	905
22.3	Dynamic Memory Allocation	906
22.4	Linked Lists	907
22.5	Stacks	917
22.6	Queues	921
22.7	Trees	924
22.8	Wrap-Up	930

## **23 Applets and Java Web Start** **941**

23.1	Introduction	942
23.2	Sample Applets Provided with the JDK	943
23.3	Simple Java Applet: Drawing a String	947
23.3.1	Executing <code>WelcomeApplet</code> in the <code>appletviewer</code>	949
23.3.2	Executing an Applet in a Web Browser	951

23.4	Applet Life-Cycle Methods	951
23.5	Initialization with Method <code>init</code>	952
23.6	Sandbox Security Model	954
23.7	Java Web Start and the Java Network Launch Protocol (JNLP)	956
23.7.1	Packaging the DrawTest Applet for Use with Java Web Start	956
23.7.2	JNLP Document for the DrawTest Applet	957
23.8	Wrap-Up	961

## **24 Multimedia: Applets and Applications** **967**

24.1	Introduction	968
24.2	Loading, Displaying and Scaling Images	969
24.3	Animating a Series of Images	975
24.4	Image Maps	982
24.5	Loading and Playing Audio Clips	985
24.6	Playing Video and Other Media with Java Media Framework	988
24.7	Wrap-Up	992
24.8	Web Resources	992

## **25 GUI Components: Part 2** **1000**

25.1	Introduction	1001
25.2	JSlider	1001
25.3	Windows: Additional Notes	1005
25.4	Using Menus with Frames	1006
25.5	JPopupMenu	1014
25.6	Pluggable Look-and-Feel	1017
25.7	JDesktopPane and JInternalFrame	1022
25.8	JTabbedPane	1026
25.9	Layout Managers: BorderLayout and GridBagLayout	1028
25.10	Wrap-Up	1040

## **26 Multithreading** **1045**

26.1	Introduction	1046
26.2	Thread States: Life Cycle of a Thread	1048
26.3	Creating and Executing Threads with Executor Framework	1051
26.4	Thread Synchronization	1054
26.4.1	Unsynchronized Data Sharing	1055
26.4.2	Synchronized Data Sharing—Making Operations Atomic	1059
26.5	Producer/Consumer Relationship without Synchronization	1062
26.6	Producer/Consumer Relationship: ArrayBlockingQueue	1070
26.7	Producer/Consumer Relationship with Synchronization	1073
26.8	Producer/Consumer Relationship: Bounded Buffers	1079
26.9	Producer/Consumer Relationship: The Lock and Condition Interfaces	1086
26.10	Concurrent Collections Overview	1093
26.11	Multithreading with GUI	1095

26.11.1	Performing Computations in a Worker Thread	1096
26.11.2	Processing Intermediate Results with <code>SwingWorker</code>	1102
26.12	Interfaces <code>Callable</code> and <code>Future</code>	1109
26.13	Java SE 7: Fork/Join Framework	1109
26.14	Wrap-Up	1110

## **27 Networking** **1118**

27.1	Introduction	1119
27.2	Manipulating URLs	1120
27.3	Reading a File on a Web Server	1125
27.4	Establishing a Simple Server Using Stream Sockets	1128
27.5	Establishing a Simple Client Using Stream Sockets	1130
27.6	Client/Server Interaction with Stream Socket Connections	1130
27.7	Datagrams: Connectionless Client/Server Interaction	1142
27.8	Client/Server Tic-Tac-Toe Using a Multithreaded Server	1150
27.9	[Web Bonus] Case Study: <code>DeitelMessenger</code>	1165
27.10	Wrap-Up	1165

## **28 Accessing Databases with JDBC** **1171**

28.1	Introduction	1172
28.2	Relational Databases	1173
28.3	Relational Database Overview: The books Database	1174
28.4	SQL	1177
28.4.1	Basic <code>SELECT</code> Query	1178
28.4.2	<code>WHERE</code> Clause	1179
28.4.3	<code>ORDER BY</code> Clause	1181
28.4.4	Merging Data from Multiple Tables: <code>INNER JOIN</code>	1182
28.4.5	<code>INSERT</code> Statement	1184
28.4.6	<code>UPDATE</code> Statement	1185
28.4.7	<code>DELETE</code> Statement	1186
28.5	Instructions for Installing MySQL and MySQL Connector/J	1186
28.6	Instructions for Setting Up a MySQL User Account	1187
28.7	Creating Database books in MySQL	1188
28.8	Manipulating Databases with JDBC	1189
28.8.1	Connecting to and Querying a Database	1189
28.8.2	Querying the books Database	1194
28.9	<code>RowSet</code> Interface	1207
28.10	Java DB/Apache Derby	1209
28.11	<code>PreparedStatement</code> s	1211
28.12	Stored Procedures	1226
28.13	Transaction Processing	1227
28.14	Wrap-Up	1227
28.15	Web Resources	1228

<b>29</b>	<b>JavaServer™ Faces Web Apps: Part 1</b>	<b>1235</b>

29.2	HyperText Transfer Protocol (HTTP) Transactions	1237
29.3	Multitier Application Architecture	1240
29.4	Your First JSF Web App	1241
29.4.1	The Default <code>index.html</code> Document: Introducing Facelets	1242
29.4.2	Examining the <code>WebTimeBean</code> Class	1244
29.4.3	Building the <code>WebTime</code> JSF Web App in NetBeans	1246
29.5	Model-View-Controller Architecture of JSF Apps	1250
29.6	Common JSF Components	1250
29.7	Validation Using JSF Standard Validators	1254
29.8	Session Tracking	1261
29.8.1	Cookies	1262
29.8.2	Session Tracking with <code>@SessionScoped</code> Beans	1263
29.9	Wrap-Up	1269
<b>30</b>	<b>JavaServer™ Faces Web Apps: Part 2</b>	<b>1276</b>
30.1	Introduction	1277
30.2	Accessing Databases in Web Apps	1277
30.2.1	Setting Up the Database	1279
30.2.2	<code>@ManagedBean</code> Class <code>AddressBean</code>	1282
30.2.3	<code>index.html</code> Facelets Page	1286
30.2.4	<code>addentry.html</code> Facelets Page	1288
30.3	Ajax	1290
30.4	Adding Ajax Functionality to the Validation App	1292
30.5	Wrap-Up	1295
<b>31</b>	<b>Web Services</b>	<b>1299</b>
31.1	Introduction	1300
31.2	Web Service Basics	1302
31.3	Simple Object Access Protocol (SOAP)	1302
31.4	Representational State Transfer (REST)	1302
31.5	JavaScript Object Notation (JSON)	1303
31.6	Publishing and Consuming SOAP-Based Web Services	1303
31.6.1	Creating a Web Application Project and Adding a Web Service Class in NetBeans	1303
31.6.2	Defining the <code>WelcomeSOAP</code> Web Service in NetBeans	1304
31.6.3	Publishing the <code>WelcomeSOAP</code> Web Service from NetBeans	1307
31.6.4	Testing the <code>WelcomeSOAP</code> Web Service with GlassFish Application Server's Tester Web Page	1308
31.6.5	Describing a Web Service with the Web Service Description Language (WSDL)	1309
31.6.6	Creating a Client to Consume the <code>WelcomeSOAP</code> Web Service	1310
31.6.7	Consuming the <code>WelcomeSOAP</code> Web Service	1312

31.7	Publishing and Consuming REST-Based XML Web Services	1315
31.7.1	Creating a REST-Based XML Web Service	1315
31.7.2	Consuming a REST-Based XML Web Service	1318
31.8	Publishing and Consuming REST-Based JSON Web Services	1320
31.8.1	Creating a REST-Based JSON Web Service	1320
31.8.2	Consuming a REST-Based JSON Web Service	1322
31.9	Session Tracking in a SOAP Web Service	1324
31.9.1	Creating a Blackjack Web Service	1325
31.9.2	Consuming the Blackjack Web Service	1328
31.10	Consuming a Database-Driven SOAP Web Service	1339
31.10.1	Creating the Reservation Database	1340
31.10.2	Creating a Web Application to Interact with the Reservation Service	1343
31.11	Equation Generator: Returning User-Defined Types	1346
31.11.1	Creating the EquationGeneratorXML Web Service	1349
31.11.2	Consuming the EquationGeneratorXML Web Service	1350

31.11.4	Consuming the EquationGeneratorJSON Web Service	1354
31.12	Wrap-Up	1357

## **A** Operator Precedence Chart **1365**

## **B** ASCII Character Set **1367**

## **C** Keywords and Reserved Words **1368**

## **D** Primitive Types **1369**

## **E** Using the Java API Documentation **1370**

E.1	Introduction	1370
E.2	Navigating the Java API	1370

## **F** Using the Debugger **1378**

F.1	Introduction	1379
F.2	Breakpoints and the run, stop, cont and print Commands	1379
F.3	The print and set Commands	1383
F.4	Controlling Execution Using the step, step up and next Commands	1385
F.5	The watch Command	1388
F.6	The clear Command	1391
F.7	Wrap-Up	1393

## **G** Formatted Output **1395**

G.1	Introduction	1396
-----	--------------	------

G.2	Streams	1396
G.3	Formatting Output with <code>printf</code>	1396
G.4	Printing Integers	1397
G.5	Printing Floating-Point Numbers	1398
G.6	Printing Strings and Characters	1400
G.7	Printing Dates and Times	1401
G.8	Other Conversion Characters	1403
G.9	Printing with Field Widths and Precisions	1405
G.10	Using Flags in the <code>printf</code> Format String	1407
G.11	Printing with Argument Indices	1411
G.12	Printing Literals and Escape Sequences	1411
G.13	Formatting Output with Class <code>Formatter</code>	1412
G.14	Wrap-Up	1413

## **H** Number Systems **1418**

H.1	Introduction	1419
H.2	Abbreviating Binary Numbers as Octal and Hexadecimal Numbers	1422
H.3	Converting Octal and Hexadecimal Numbers to Binary Numbers	1423
H.4	Converting from Binary, Octal or Hexadecimal to Decimal	1423
H.5	Converting from Decimal to Binary, Octal or Hexadecimal	1424
H.6	Negative Binary Numbers: Two's Complement Notation	1426

## **I** GroupLayout **1431**

I.1	Introduction	1431
I.2	GroupLayout Basics	1431
I.3	Building a <code>ColorChooser</code>	1432
I.4	GroupLayout Web Resources	1442

## **J** Java Desktop Integration Components **1443**

J.1	Introduction	1443
J.2	Splash Screens	1443
J.3	Desktop Class	1445
J.4	Tray Icons	1447

## **K** Mashups **1449**

K.1	Introduction	1449
K.2	Popular Mashups	1449
K.3	APIs Commonly Used in Mashups	1450
K.4	Deitel Mashups Resource Center	1450
K.5	Deitel RSS Resource Center	1451
K.6	Mashup Performance and Reliability Issues	1451

## **L** Unicode® **1452**

L.1	Introduction	1452
-----	--------------	------

L.2	Unicode Transformation Formats	1453
L.3	Characters and Glyphs	1454
L.4	Advantages/Disadvantages of Unicode	1454
L.5	Using Unicode	1455
L.6	Character Ranges	1457

## **Appendices on the Web** **1459**

## **Index** **1461**

Appendices M–Q are PDF documents posted online at the book’s Companion Website ([www.pearsonhighered.com/deitel/](http://www.pearsonhighered.com/deitel/)).

# Preface

*Live in fragments no longer, only connect.*  
—Edgar Morgan Foster

Welcome to Java and *Java How to Program, Ninth Edition*! This book presents leading-edge computing technologies for students, instructors and software developers.

The new Chapter 1 engages students with intriguing facts and figures to get them excited about studying computers and programming. The chapter includes a table of some of the research made possible by computers; current technology trends and hardware discussion; the data hierarchy; a table of mobile and Internet app platforms; a new section on social networking; an introduction to Android; a table of popular web services; a table of business and technology publications and websites that will help you stay up to date with the latest technology news and trends; and updated exercises.

The book is appropriate for introductory course sequences based on the ACM/IEEE curriculum recommendations and for AP Computer Science exam preparation.

We focus on software engineering best practices. At the heart of the book is the Deitel signature “live-code approach”—concepts are presented in the context of complete working programs, rather than in code snippets. Each complete code example is accompanied by live sample executions. All the source code is available at [www.deitel.com/books/jhtp9/](http://www.deitel.com/books/jhtp9/) and at the book’s Companion Website [www.pearsonhighered.com/deitel/](http://www.pearsonhighered.com/deitel/).

As you read the book, if you have questions, send an e-mail to [deitel@deitel.com](mailto:deitel@deitel.com); we’ll respond promptly. For updates on this book, visit [www.deitel.com/books/jhtp9/](http://www.deitel.com/books/jhtp9/), follow us on Facebook ([www.deitel.com/deitelfan](http://www.deitel.com/deitelfan)) and Twitter (@deitel), and subscribe to the *Deitel*<sup>®</sup> *Buzz Online* newsletter ([www.deitel.com/newsletter/subscribe.html](http://www.deitel.com/newsletter/subscribe.html)).

## New and Updated Features

Here are the updates we’ve made for *Java How to Program, 9/e*:

### *Java Standard Edition (SE) 7*

- *Easy to use as a Java SE 6 or Java SE 7 book.* There are a few Java Standard Edition (SE) 7 features that affect CS 1 and CS 2 courses. We cover those features in optional modular sections that are easy to include or omit. Here’s some of the new functionality: Strings in switch statements, the try-with-resources statement for managing AutoCloseable objects, multi-catch for defining a single exception handler to replace multiple exception handlers that perform the same task, the NIO filesystem APIs and inferring the types of generic objects from the variable they’re assigned to by using the <> notation. We also overview the new concurrency API features.

- *Java SE 7 filesystem APIs.* We provide an *alternate* online version of Chapter 17, Files, Streams and Object Serialization, that's reimplemented with the new filesystem APIs from Java SE 7.
- *Java SE 7's AutoClosable versions of Connection, Statement and ResultSet.* With the source code for Chapter 28, Accessing Databases with JDBC, we provide a version of the chapter's first example that's implemented using Java SE 7's AutoClosable versions of Connection, Statement and ResultSet. AutoClosable objects reduce the likelihood of resource leaks when you use them with Java SE 7's try-with-resources statement, which automatically closes the AutoClosable objects allocated in the parentheses following the try keyword.

### *Pedagogic Features*

- *Enhanced Making a Difference exercises set.* We encourage you to use computers and the Internet to research and solve significant social problems. These exercises are meant to increase awareness and discussion of important issues the world is facing. We hope you'll approach them with your own values, politics and beliefs. Check out our new Making a Difference Resource Center at [www.deitel.com/MakingADifference](http://www.deitel.com/MakingADifference) for additional ideas you may want to investigate further.
- *Page numbers for key terms in chapter summaries.* For key terms that appear in the chapter summaries, we include the page number of the key term's defining occurrence.
- *VideoNotes.* The Companion Website includes extensive VideoNotes in which co-author Paul Deitel explains in detail most of the programs in the core chapters. Instructors have told us that their students find the VideoNotes valuable.

### *Object Technology*

- *Object-oriented programming and design.* We introduce the basic concepts and terminology of object technology in Chapter 1. Students develop their first customized classes and objects in Chapter 3. Presenting objects and classes early gets students "thinking about objects" immediately and mastering these concepts more thoroughly. [For courses that require a late-objects approach, consider *Java How to Program, Late Objects Version, 8/e*, which begins with six chapters on programming fundamentals (including two on control statements) and continues with seven chapters that gradually introduce object-oriented programming concepts.]
- *Exception handling.* We integrate basic exception handling earlier in the book and instructors can easily pull more material forward from Chapter 11, Exception Handling: A Deeper Look.
- *Class Arrays and ArrayList.* Chapter 7 covers class Arrays—which contains methods for performing common array manipulations—and class ArrayList—which implements a dynamically resizable array-like data structure. This follows our philosophy of getting lots of practice *using existing classes while learning how to define your own classes*.
- *OO case studies.* The early classes and objects presentation features Time, Employee and GradeBook class case studies that weave their way through multiple sections and chapters, gradually introducing deeper OO concepts.

- *Optional Case Study: Using the UML to Develop an Object-Oriented Design and Java Implementation of an ATM.* The UML™ (Unified Modeling Language™) is the industry-standard graphical language for modeling object-oriented systems. Chapters 12–13 include an *optional* case study on object-oriented design using the UML. We design and implement the software for a simple automated teller machine (ATM). We analyze a typical requirements document that specifies the system to be built. We determine the classes needed to implement that system, the attributes the classes need to have, the behaviors the classes need to exhibit and specify how the classes must interact with one another to meet the system requirements. From the design we produce a *complete* Java implementation. Students often report having a “light-bulb moment”—the case study helps them “tie it all together” and really understand object orientation.
- *Reordered data structures presentation.* We begin with generic class `ArrayList` in Chapter 7. Because *students will understand basic generics concepts early in the book*, our later data structures discussions provide a deeper treatment of generic collections—showing how to use the built-in collections of the Java API. We then show how to implement generic methods and classes. Finally, we show how to build custom generic data structures.

### Database and Web Development

- *JDBC 4.* Chapter 28, Accessing Databases with JDBC, covers JDBC 4 and uses the Java DB/Apache Derby and MySQL database management systems. The chapter features an OO case study on developing a database-driven address book that demonstrates prepared statements and JDBC 4’s automatic driver discovery.
- *Java Server Faces (JSF) 2.0.* Chapters 29–30 have been updated to introduce JavaServer Faces (JSF) 2.0 technology, which greatly simplifies building JSF web applications. Chapter 29 includes examples on building web application GUIs, validating forms and session tracking. Chapter 30 discusses data-driven and Ajax-enabled JSF applications. The chapter features a database-driven multitier web address book that allows users to add and search for contacts. This Ajax-enabled application gives the reader a nice sense of Web 2.0 software development.
- *Web services.* Chapter 31, Web Services, demonstrates creating and consuming SOAP- and REST-based web services. Case studies include developing blackjack and airline reservation web services.
- *Java Web Start and the Java Network Launch Protocol (JNLP).* We introduce Java Web Start and JNLP, which enable applets *and* applications to be launched via a web browser. Users can install locally for later execution. Programs can also request the user’s permission to access local system resources such as files—enabling you to develop more robust applets and applications that execute safely using Java’s sandbox security model, which applies to downloaded code.

### Multithreading

- *Multithreading.* We completely reworked Chapter 26, Multithreading [special thanks to the guidance of Brian Goetz and Joseph Bowbeer—two of the co-authors of *Java Concurrency in Practice*, Addison-Wesley, 2006].
- *SwingWorker class.* We use class `SwingWorker` to create *multithreaded user interfaces*.

### GUI and Graphics

- *Scalable GUI and graphics presentation.* Instructors teaching introductory courses have a broad choice of the amount of GUI and graphics to cover—from none, to an optional 10-brief-sections introductory sequence woven in with the early chapters, to a deep treatment in Chapters 14, 15 and 25, and Appendix I.
- *GroupLayout layout manager.* We discuss the GroupLayout layout manager in the context of the GUI design tool in the NetBeans IDE.
- *JTable sorting and filtering capabilities.* Chapter 28 uses these capabilities to re-sort the data in a JTable and filter it by regular expressions.

### Other Features

- *Android.* Because of the tremendous interest in Android-based smartphones and tablets, we've included a three-chapter introduction to Android app development on the Companion Website. These chapters are from our new Deitel Developer Series book *Android for Programmers: An App-Driven Approach*. After you learn Java, you'll find it straightforward to develop and run Android apps on the free Android emulator that you can download from [developer.android.com](http://developer.android.com).
- *Software engineering community concepts.* We discuss agile software development, refactoring, design patterns, LAMP, SaaS (Software as a Service), PaaS (Platform as a Service), cloud computing, open-source software and more.

## Dependency Chart

The chart on the next page shows the dependencies among the chapters to help instructors plan their syllabi. *Java How to Program, 9/e*, is appropriate for a variety of programming courses at various levels, most notably CS 1 and CS 2 courses and introductory course sequences in related disciplines. The book has a clearly delineated, modular organization. Chapters 1–11 and 14–17 form an accessible elementary programming sequence with a solid introduction to object-oriented programming. *Optional* Chapters 12–13 form an accessible introduction to object-oriented design with the UML. The GUI and Graphics Track and Chapters 14, 15, 23, 24 and 25 form a substantial GUI, graphics and multimedia sequence. Chapters 18–22 form a nice data-structures sequence. Chapters 26–27 form a solid introduction to multithreading and Internet networking. Chapters 28–31 form a rich database-intensive web application development sequence.

## Teaching Approach

*Java How to Program, 9/e*, contains hundreds of complete working examples. We stress program clarity and concentrate on building well-engineered software.

*Syntax Coloring.* For readability, we syntax color all the Java code, similar to the way most Java integrated-development environments and code editors syntax color code. Our syntax-coloring conventions are as follows:

```

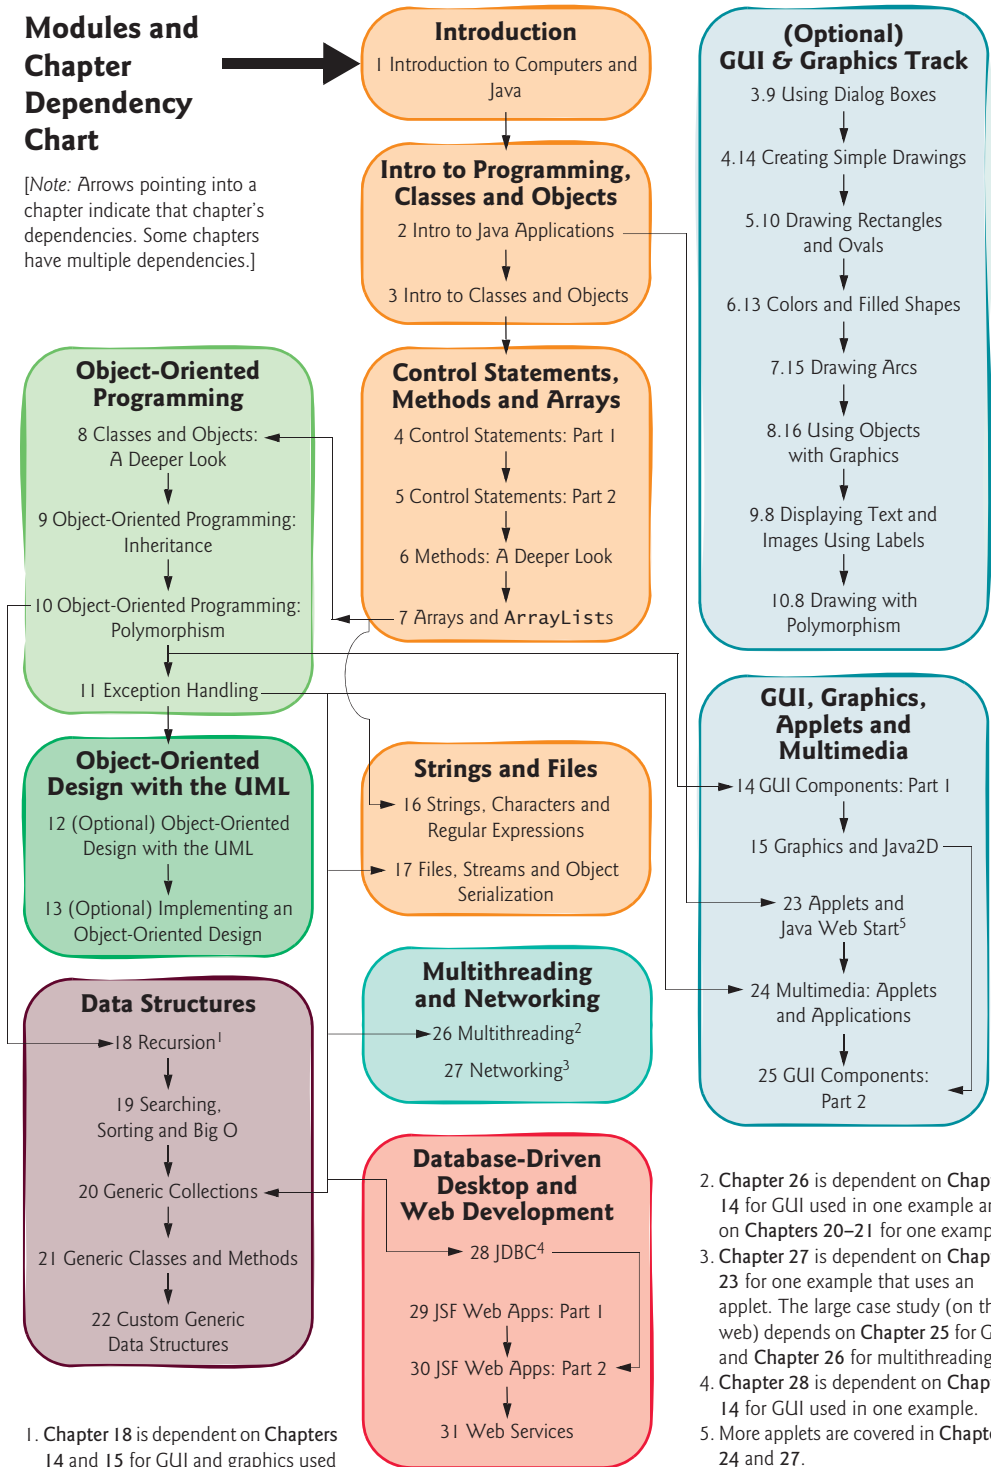

comments appear in green
keywords appear in dark blue
errors appear in red
constants and literal values appear in light blue
all other code appears in black

# Modules and Chapter Dependency Chart

[Note: Arrows pointing into a chapter indicate that chapter's dependencies. Some chapters have multiple dependencies.]

1. Chapter 18 is dependent on Chapters 14 and 15 for GUI and graphics used in one example.

2. Chapter 26 is dependent on Chapter 14 for GUI used in one example and on Chapters 20–21 for one example.  
 3. Chapter 27 is dependent on Chapter 23 for one example that uses an applet. The large case study (on the web) depends on Chapter 25 for GUI and Chapter 26 for multithreading.  
 4. Chapter 28 is dependent on Chapter 14 for GUI used in one example.  
 5. More applets are covered in Chapters 24 and 27.

*Code Highlighting.* We place yellow rectangles around key code segments.

*Using Fonts for Emphasis.* We place the key terms and the index's page reference for each defining occurrence in **bold maroon** text for easier reference. We emphasize on-screen components in the **bold Helvetica** font (e.g., the **File** menu) and emphasize Java program text in the Lucida font (for example, `int x = 5;`).

*Web Access.* All of the source-code examples can be downloaded from:

[www.deitel.com/books/jhttp9](http://www.deitel.com/books/jhttp9)  
[www.pearsonhighered.com/deitel](http://www.pearsonhighered.com/deitel)

*Objectives.* The opening quotes are followed by a list of chapter objectives.

*Illustrations/Figures.* Abundant tables, line drawings, UML diagrams, programs and program outputs are included.

*Programming Tips.* We include programming tips to help you focus on important aspects of program development. These tips and practices represent the best we've gleaned from a combined seven decades of programming and teaching experience.

### Good Programming Practices

*The Good Programming Practices call attention to techniques that will help you produce programs that are clearer, more understandable and more maintainable.*

### Common Programming Errors

*Pointing out these Common Programming Errors reduces the likelihood that you'll make them.*

### Error-Prevention Tips

*These tips contain suggestions for exposing bugs and removing them from your programs; many describe aspects of Java that prevent bugs from getting into programs in the first place.*

### Performance Tips

*These tips highlight opportunities for making your programs run faster or minimizing the amount of memory that they occupy.*

### Portability Tips

*The Portability Tips help you write code that will run on a variety of platforms.*

### Software Engineering Observations

*The Software Engineering Observations highlight architectural and design issues that affect the construction of software systems, especially large-scale systems.*

### Look-and-Feel Observations

*The Look-and-Feel Observations highlight graphical-user-interface conventions. These observations help you design attractive, user-friendly graphical user interfaces that conform to industry norms.*

*Summary Bullets.* We present a section-by-section bullet-list summary of the chapter. For ease of reference, we include the page number of each key term's defining occurrence in the text.

*Self-Review Exercises and Answers.* Extensive self-review exercises *and* answers are included for self study. All of the exercises in the optional ATM case study are fully solved.

*Exercises.* The chapter exercises include:

- simple recall of important terminology and concepts
- What's wrong with this code?
- What does this code do?
- writing individual statements and small portions of methods and classes
- writing complete methods, classes and programs
- major projects
- in many chapters, Making a Difference exercises.

*Index.* We've included an extensive index. Defining occurrences of key terms are highlighted with a **bold maroon** page number.

## Software Used in Java How to Program, 9/e

All the software you'll need for this book is available free for download from the web. See the Before You Begin section that follows this Preface for links to each download.

We wrote most of the examples in *Java How to Program, 9/e*, using the free Java Standard Edition Development Kit (JDK) 6. For the optional Java SE 7 modules, we used the OpenJDK's early access version of JDK 7. In Chapters 29–31, we also used the Netbeans IDE, and in Chapter 28, we used MySQL and MySQL Connector/J. You can find additional resources and software downloads in our Java Resource Centers at:

[www.deitel.com/ResourceCenters.html](http://www.deitel.com/ResourceCenters.html)

## Java IDE Resource Kit

Your instructor may have ordered through your college bookstore a Value Pack edition of *Java How to Program, 9/e* that comes bundled with the Java IDE Resource Kit. This kit contains CD or DVD versions of Java™ SE Development Kit 6 for Windows®, Eclipse™ IDE for Windows®, NetBeans™ IDE, jGRASP™ IDE, DrJava IDE, BlueJ IDE and the TextPad® Text Editor for Windows®. Free versions of these IDEs also can be downloaded from the web. The Java IDE Resource Kit also includes access to a Companion Website containing step-by-step VideoNotes and written instructions to help you get started with each development environment. If your book did not come with the Java IDE Resource Kit, you can purchase access to the Resource Kit's Companion Website from [www.pearsonhighered.com/javaidokit/](http://www.pearsonhighered.com/javaidokit/). You'll still need to download the free software separately.

## Discounts on Deitel Developer Series Books

If you'd like to receive information on professional *Deitel Developer Series* titles, including *Android for Programmers: An App-Driven Approach*, please register your copy of *Java How*

to Program, *9/e* at [informit.com/register](http://informit.com/register). You'll receive information on how to purchase *Android for Programmers* at a discount.

## CourseSmart Web Books

Today's students and instructors have increasing demands on their time and money. Pearson has responded to that need by offering digital texts and course materials online through CourseSmart. CourseSmart allows faculty to review course materials online, saving time and costs. It offers students a high-quality digital version of the text for less than the cost of a print copy of the text. Students receive the same content offered in the print textbook enhanced by search, note-taking, and printing tools. For more information, visit [www.coursesmart.com](http://www.coursesmart.com).

## Instructor Supplements

*The following supplements are available to qualified instructors only* through Pearson Education's Instructor Resource Center ([www.pearsonhighered.com/irc](http://www.pearsonhighered.com/irc)):

- *PowerPoint® slides* containing all the code and figures in the text, plus bulleted items that summarize key points.
- *Test Item File* of multiple-choice questions (approximately two per book section).
- *Solutions Manual* with solutions to the vast majority of the end-of-chapter exercises.

Please do not write to us requesting access to the Pearson Instructor's Resource Center which contains the book's instructor supplements, including the exercise solutions. Access is limited strictly to college instructors teaching from the book. Instructors may obtain access only through their Pearson representatives. Solutions are *not* provided for "project" exercises. Check out our Programming Projects Resource Center for lots of additional exercise and project possibilities ([www.deitel.com/ProgrammingProjects/](http://www.deitel.com/ProgrammingProjects/)).

If you're not a registered faculty member, contact your Pearson representative or visit [www.pearsonhighered.com/educator/replocator/](http://www.pearsonhighered.com/educator/replocator/).

## Acknowledgments

We'd like to thank Abbey Deitel and Barbara Deitel for long hours devoted to this project. We're fortunate to have worked on this project with the dedicated team of publishing professionals at Pearson. We appreciate the guidance, savvy and energy of Michael Hirsch, Editor-in-Chief of Computer Science. Carole Snyder recruited the book's reviewers and managed the review process. Bob Engelhardt managed the book's production.

### Reviewers

We wish to acknowledge the efforts of our eighth and ninth edition reviewers. They scrutinized the text and the programs and provided countless suggestions for improving the presentation: Lance Andersen (Oracle), Soundararajan Angusamy (Sun Microsystems), Joseph Bowbeer (Consultant), William E. Duncan (Louisiana State University), Diana Franklin (University of California, Santa Barbara), Edward F. Gehringer (North Carolina State University), Huiwei Guan (Northshore Community College), Ric Heishman (George Mason University), Dr. Heinz Kabutz (JavaSpecialists.eu), Patty Kraft (San Diego State University), Lawrence Premkumar (Sun Microsystems), Tim Margush (Univer-

sity of Akron), Sue McFarland Metzger (Villanova University), Shyamal Mitra (The University of Texas at Austin), Peter Pilgrim (Consultant), Manjeet Rege, Ph.D. (Rochester Institute of Technology), Manfred Riem (Java Champion, Consultant, Robert Half), Simon Ritter (Oracle), Susan Rodger (Duke University), Amr Sabry (Indiana University), José Antonio González Seco (Parliament of Andalusia), Sang Shin (Sun Microsystems), S. Sivakumar (Astra Infotech Private Limited), Raghavan “Rags” Srinivas (Intuit), Monica Sweat (Georgia Tech), Vinod Varma (Astra Infotech Private Limited) and Alexander Zuev (Sun Microsystems).

Well, there you have it! As you read the book, we’d appreciate your comments, criticisms, corrections and suggestions for improvement. Please address all correspondence to:

`deitel@deitel.com`

We’ll respond promptly. We hope you enjoy working with *Java How to Program, 9/e*. Good luck!

*Paul and Harvey Deitel*

## About the Authors

**Paul J. Deitel**, CEO and Chief Technical Officer of Deitel & Associates, Inc., is a graduate of MIT, where he studied Information Technology. Through Deitel & Associates, Inc., he has delivered hundreds of Java, C++, C, C#, Visual Basic and Internet programming courses to industry clients, including Cisco, IBM, Siemens, Sun Microsystems, Dell, Lucent Technologies, Fidelity, NASA at the Kennedy Space Center, the National Severe Storm Laboratory, White Sands Missile Range, Rogue Wave Software, Boeing, SunGard Higher Education, Stratus, Cambridge Technology Partners, One Wave, Hyperion Software, Adra Systems, Entergy, CableData Systems, Nortel Networks, Puma, iRobot, Invensys and many more. He and his co-author, Dr. Harvey M. Deitel, are the world’s best-selling programming-language textbook authors.

**Dr. Harvey M. Deitel**, Chairman and Chief Strategy Officer of Deitel & Associates, Inc., has 50 years of experience in the computer field. Dr. Deitel earned B.S. and M.S. degrees from MIT and a Ph.D. from Boston University. He has extensive college teaching experience, including earning tenure and serving as the Chairman of the Computer Science Department at Boston College before founding Deitel & Associates, Inc., with his son, Paul J. Deitel. He and Paul are the co-authors of dozens of books and LiveLessons multimedia packages and they are writing many more. The Deitels’ texts have earned international recognition, with translations published in Japanese, German, Russian, Chinese, Spanish, Korean, French, Polish, Italian, Portuguese, Greek, Urdu and Turkish. Dr. Deitel has delivered hundreds of professional programming seminars to major corporations, academic institutions, government organizations and the military.

## Corporate Training from Deitel & Associates, Inc.

Deitel & Associates, Inc., is an internationally recognized corporate training and authoring organization. The company provides instructor-led courses delivered at client sites worldwide on major programming languages and platforms, such as Java™, C++, Visual C++®, C, Visual C#®, Visual Basic®, XML®, Python®, object technology, Internet and web programming, Android™ and iPhone® app development, and a growing list of additional programming and software-development courses. The founders of Deitel & Associates,

Inc., are Paul J. Deitel and Dr. Harvey M. Deitel. The company's clients include many of the world's largest companies, government agencies, branches of the military, and academic institutions. Through its 35-year publishing partnership with Prentice Hall/Pearson, Deitel & Associates, Inc., publishes leading-edge programming textbooks, professional books and *LiveLessons* DVD-based and web-based video courses. Deitel & Associates, Inc., and the authors can be reached via e-mail at:

[deitel@deitel.com](mailto:deitel@deitel.com)

To learn more about Deitel & Associates, Inc., its publications and its *Dive Into*<sup>®</sup> *Series* Corporate Training curriculum delivered at client locations worldwide, visit:

[www.deitel.com/training/](http://www.deitel.com/training/)

and subscribe to the free *Deitel*<sup>®</sup> *Buzz Online* e-mail newsletter at:

[www.deitel.com/newsletter/subscribe.html](http://www.deitel.com/newsletter/subscribe.html)

and follow the authors on Facebook ([www.deitel.com/deitel/fan](http://www.deitel.com/deitel/fan)) and Twitter (@deitel).

Individuals wishing to purchase Deitel books, and *LiveLessons* DVD and web-based training courses can do so through [www.deitel.com](http://www.deitel.com). Bulk orders by corporations, the government, the military and academic institutions should be placed directly with Pearson. For more information, visit

[www.pearsonhighered.com](http://www.pearsonhighered.com)

# Before You Begin

This section contains information you should review before using this book and instructions to ensure that your computer is set up properly for use with this book. We'll post updates (if any) to the Before You Begin section on the book's website:

[www.deitel.com/books/jhttp9/](http://www.deitel.com/books/jhttp9/)

## Font and Naming Conventions

We use fonts to distinguish between on-screen components (such as menu names and menu items) and Java code or commands. Our convention is to emphasize on-screen components in a sans-serif bold Helvetica font (for example, **File** menu) and to emphasize Java code and commands in a sans-serif Lucida font (for example, `System.out.println()`).

## Software Used in the Book

All the software you'll need for this book is available free for download from the web.

### *Java SE Software Development Kit (JDK) 6 and 7*

We wrote most of the examples in *Java How to Program, 9/e*, using the free Java Standard Edition Development Kit (JDK) 6, which is available from:

[www.oracle.com/technetwork/java/javase/downloads/index.html](http://www.oracle.com/technetwork/java/javase/downloads/index.html)

For the optional Java SE 7 modules, we used the OpenJDK's early access version of JDK 7, which is available from:

[dlc.sun.com.edgesuite.net/jdk7/binaries-/index.html](http://dlc.sun.com.edgesuite.net/jdk7/binaries-/index.html)

### *Java DB, MySQL and MySQL Connector/J*

In Chapter 28, we use the Java DB and MySQL Community Edition database management systems. Java DB is part of the JDK installation. At the time of this writing, the JDK's 64-bit installer was not properly installing Java DB. If you are using the 64-bit version of Java, you may need to install Java DB separately. You can download Java DB from:

[www.oracle.com/technetwork/java/javadb/downloads/index.html](http://www.oracle.com/technetwork/java/javadb/downloads/index.html)

At the time of this writing, the latest release of MySQL Community Edition was 5.5.8. To install MySQL Community Edition on Windows, Linux or Mac OS X, see the installation overview for your platform at:

- Windows: [dev.mysql.com/doc/refman/5.5/en/windows-installation.html](http://dev.mysql.com/doc/refman/5.5/en/windows-installation.html)
- Linux: [dev.mysql.com/doc/refman/5.5/en/linux-installation-rpm.html](http://dev.mysql.com/doc/refman/5.5/en/linux-installation-rpm.html)
- Mac OS X: [dev.mysql.com/doc/refman/5.5/en/macosx-installation.html](http://dev.mysql.com/doc/refman/5.5/en/macosx-installation.html)

Carefully follow the instructions for downloading and installing the software on your platform. The downloads are available from:

[dev.mysql.com/downloads/mysql/](http://dev.mysql.com/downloads/mysql/)

You also need to install **MySQL Connector/J** (the J stands for Java), which allows programs to use JDBC to interact with MySQL. MySQL Connector/J can be downloaded from

[dev.mysql.com/downloads/connector/j/](http://dev.mysql.com/downloads/connector/j/)

At the time of this writing, the current generally available release of MySQL Connector/J is 5.1.14. The documentation for Connector/J is located at

[dev.mysql.com/doc/refman/5.5/en/connector-j.html](http://dev.mysql.com/doc/refman/5.5/en/connector-j.html)

To install MySQL Connector/J, carefully follow the installation instructions at:

[dev.mysql.com/doc/refman/5.5/en/connector-j-installing.html](http://dev.mysql.com/doc/refman/5.5/en/connector-j-installing.html)

We *do not* recommend modifying your system's CLASSPATH environment variable, which is discussed in the installation instructions. Instead, we'll show you how use MySQL Connector/J by specifying it as a command-line option when you execute your applications.

## Java IDE Resource Kit

Your instructor may have ordered through your college bookstore a Value Pack edition of *Java How to Program, 9/e* that comes bundled with the Java IDE Resource Kit. This kit contains CD or DVD versions of Java™ SE Development Kit 6 (JDK 6) for Windows®, Eclipse™ IDE for Windows®, NetBeans™ IDE, jGRASP™ IDE, DrJava IDE, BlueJ IDE and the TextPad® Text Editor for Windows®. Free versions of these IDEs also can be downloaded from the web at the following sites:

- JDK 6: [www.oracle.com/technetwork/java/javase/downloads/](http://www.oracle.com/technetwork/java/javase/downloads/)
- Eclipse IDE: [eclipse.org/downloads/](http://eclipse.org/downloads/)
- NetBeans IDE: [netbeans.org/downloads/](http://netbeans.org/downloads/)
- jGRASP IDE: [spider.eng.auburn.edu/user-cgi/grasp/grasp.pl?d1=download\\_jgrasp.html](http://spider.eng.auburn.edu/user-cgi/grasp/grasp.pl?d1=download_jgrasp.html)
- DrJava IDE: [drjava.org](http://drjava.org)
- BlueJ IDE: [www.bluej.org/download/download.html](http://www.bluej.org/download/download.html)
- TextPad Text Editor (evaluation version): [www.textpad.com/download/](http://www.textpad.com/download/)

## Obtaining the Code Examples

The examples for *Java How to Program, 9/e* are available for download at

[www.deitel.com/books/jhttp9/](http://www.deitel.com/books/jhttp9/)

If you're not already registered at our website, go to [www.deitel.com](http://www.deitel.com) and click the **Register** link below our logo in the upper-left corner of the page. Fill in your information. There's no charge to register, and we do not share your information with anyone. We send you only account-management e-mails unless you register separately for our free *Deitel® Buzz Online* e-mail newsletter at [www.deitel.com/newsletter/subscribe.html](http://www.deitel.com/newsletter/subscribe.html). After registering for

the site, you'll receive a confirmation e-mail with your verification code. *Click the link in the confirmation e-mail to complete your registration.* Configure your e-mail client to allow e-mails from `deitel.com` to ensure that the confirmation email is not filtered as junk mail.

Next, go to `www.deitel.com` and sign in using the **Login** link below our logo in the upper-left corner of the page. Go to `www.deitel.com/books/jhtp9/`. You'll find the link to download the examples under the heading **Download Code Examples and Other Premium Content for Registered Users**. Write down the location where you choose to save the ZIP file on your computer.

We assume the examples are located at `C:\Examples` on your computer. Extract the contents of `Examples.zip` using a tool such as WinZip (`www.winzip.com`) or the built-in capabilities of your operating system.

## Setting the PATH Environment Variable

The PATH environment variable on your computer designates which directories the computer searches when looking for applications, such as the applications that enable you to compile and run your Java applications (called `javac` and `java`, respectively). *Carefully follow the installation instructions for Java on your platform to ensure that you set the PATH environment variable correctly.*

If you do not set the PATH variable correctly, when you use the JDK's tools, you'll receive a message like:

```
'java' is not recognized as an internal or external command,
operable program or batch file.
```

In this case, go back to the installation instructions for setting the PATH and recheck your steps. If you've downloaded a newer version of the JDK, you may need to change the name of the JDK's installation directory in the PATH variable.

## Setting the CLASSPATH Environment Variable

If you attempt to run a Java program and receive a message like

```
Exception in thread "main" java.lang.NoClassDefFoundError: YourClass
```

then your system has a CLASSPATH environment variable that must be modified. To fix the preceding error, follow the steps in setting the PATH environment variable, to locate the CLASSPATH variable, then edit the variable's value to include the local directory—typically represented as a dot (`.`). On Windows add

```
.;
```

at the beginning of the CLASSPATH's value (with no spaces before or after these characters). On other platforms, replace the semicolon with the appropriate path separator characters—often a colon (`:`)

## Java's Nimbus Look-and-Feel

Java comes bundled with an elegant, cross-platform look-and-feel known as Nimbus. For programs with graphical user interfaces, we've configured our systems to use Nimbus as the default look-and-feel.

To set Nimbus as the default for all Java applications, you must create a text file named `swing.properties` in the `lib` folder of both your JDK installation folder and your JRE installation folder. Place the following line of code in the file:

```
swing.defaultlaf=com.sun.java.swing.plaf.nimbus.NimbusLookAndFeel
```

For more information on locating these installation folders visit [java.sun.com/javase/6/webnotes/install/index.html](http://java.sun.com/javase/6/webnotes/install/index.html). [*Note:* In addition to the standalone JRE, there's a JRE nested in your JDK's installation folder. If you're using an IDE that depends on the JDK (e.g., NetBeans), you may also need to place the `swing.properties` file in the nested `jre` folder's `lib` folder.]

You're now ready to begin your Java studies with *Java How to Program, 9/e*. We hope you enjoy the book!

# Introduction to Computers and Java

# I

*Man is still the most extraordinary computer of all.*

—John F. Kennedy

*Good design is good business.*

—Thomas J. Watson, Founder of IBM

*How wonderful it is that nobody need wait a single moment before starting to improve the world.*

—Anne Frank

## Objectives

In this chapter you'll learn:

- Exciting recent developments in the computer field.
- Computer hardware, software and networking basics.
- The data hierarchy.
- The different types of programming languages.
- Basic object-technology concepts.
- The importance of the Internet and the web.
- A typical Java program-development environment.
- To test-drive a Java application.
- Some key recent software technologies.
- How computers can help you make a difference.

- |   |  |

## 1.1 Introduction

Welcome to Java—the world’s most widely used computer programming language. You’re already familiar with the powerful tasks computers perform. Using this textbook, you’ll write instructions commanding computers to perform those kinds of tasks. *Software* (i.e., the instructions you write) controls *hardware* (i.e., computers).

You’ll learn *object-oriented programming*—today’s key programming methodology. You’ll create and work with many *software objects* in this text.

Java is the preferred language for meeting many organizations’ enterprise programming needs. Java has also become the language of choice for implementing Internet-based applications and software for devices that communicate over a network.

In use today are more than a billion general-purpose computers and billions more Java-enabled cell phones, smartphones and handheld devices (such as tablet computers). According to a study by eMarketer, the number of mobile Internet users will reach approximately 134 million by 2013.<sup>1</sup> Other studies have projected smartphone sales to surpass personal computer sales in 2011<sup>2</sup> and tablet sales to account for over 20% of all personal computer sales by 2015.<sup>3</sup> By 2014, the smartphone applications market is expected to exceed \$40 billion,<sup>4</sup> which is creating significant opportunities for programming mobile applications.

### *Java Editions: SE, EE and ME*

Java has evolved so rapidly that this ninth edition of *Java How to Program*—based on **Java Standard Edition 6 (Java SE 6)** with optional modules on the new features of **Java SE 7**—was published just 14 years after the first edition. Java is used in such a broad spectrum of applications that it has two other editions. The **Java Enterprise Edition (Java EE)** is geared toward developing large-scale, distributed networking applications and web-based applications. In the past, most computer applications ran on “standalone” computers (comput-

 4. *Inc.*, December 2010/January 2011, pages 116–123.

ers that were not networked together). Today’s applications can be written with the aim of communicating among the world’s computers via the Internet and the web. Later in this book we discuss how to build such web-based applications with Java.

The **Java Micro Edition (Java ME)** is geared toward developing applications for small, memory-constrained devices, such as BlackBerry smartphones. Google’s Android operating system—used on numerous smartphones, tablets (small, lightweight mobile computers with touch screens), e-readers and other devices—uses a customized version of Java not based on Java ME.

### *Computing in Industry and Research*

These are exciting times in the computer field. Many of the most influential and successful businesses of the last two decades are technology companies, including Apple, IBM, Hewlett Packard, Dell, Intel, Motorola, Cisco, Microsoft, Google, Amazon, Facebook, Twitter, Groupon, Foursquare, Yahoo!, eBay and many more—these are major employers of people who study computer science, information systems or related disciplines. At the time of this writing, Apple was the second most valuable company in the world and *the* most valuable technology company.<sup>5</sup> Computers are also used extensively in academic and industrial research. Figure 1.1 provides just a few examples of exciting ways in which computers are used in research and industry.

Name	Description
Internet	The Internet—a global network of computers—was made possible by the <i>convergence of computing and communications</i> . It has its roots in the 1960s, when research funding was supplied by the U.S. Department of Defense. Originally designed to connect the main computer systems of about a dozen universities and research organizations, the Internet today is accessible by billions of computers and computer-controlled devices worldwide. Computers break lengthy transmissions into packets at the sending end, route the packets to their intended receivers and ensure that those packets are received in sequence and without error at the receiving end. According to a study by Forrester Research, the average U.S. online consumer now spends as much time online as watching television ( <a href="http://forrester.com/rb/Research/understanding_changing_needs_of_us_online_consumer/q/id/57861/t/2">forrester.com/rb/Research/understanding_changing_needs_of_us_online_consumer/q/id/57861/t/2</a> ).
Human Genome Project	The Human Genome Project was founded to identify and analyze the 20,000+ genes in human DNA. The project used computer programs to analyze complex genetic data, determine the sequences of the billions of chemical base pairs that make up human DNA and store the information in databases which have been made available to researchers in many fields. This research has led to tremendous innovation and growth in the biotechnology industry.

**Fig. 1.1** | A few uses for computers. (Part 1 of 3.)

5. [www.zdnet.com/blog/apple/apple-becomes-worlds-second-most-valuable-company/9047](http://www.zdnet.com/blog/apple/apple-becomes-worlds-second-most-valuable-company/9047).

Name	Description
World Community Grid	World Community Grid ( <a href="http://www.worldcommunitygrid.org">www.worldcommunitygrid.org</a> ) is a non-profit computing grid. People worldwide donate their unused computer processing power by installing a free secure software program that allows the World Community Grid to harness the excess power when the computers are idle. The computing power is used in place of supercomputers to conduct scientific research projects that are making a difference, including developing affordable solar energy, providing clean water to the developing world, fighting cancer, curing muscular dystrophy, finding influenza antiviral drugs, growing more nutritious rice for regions fighting hunger and more.
Medical imaging	X-ray computed tomography (CT) scans, also called CAT (computerized axial tomography) scans, take X-rays of the body from hundreds of different angles. Computers are used to adjust the intensity of the X-ray, optimizing the scan for each type of tissue, then to combine all of the information to create a 3D image.
GPS	Global Positioning System (GPS) devices use a network of satellites to retrieve location-based information. Multiple satellites send time-stamped signals to the device GPS device, which calculates the distance to each satellite based on the time the signal left the satellite and the time the signal was received. The location of each satellite and the distance to each are used to determine the exact location of the device. Based on your location, GPS devices can provide step-by-step directions, help you easily find nearby businesses (restaurants, gas stations, etc.) and points of interest, or help you find your friends.
Microsoft's SYNC <sup>®</sup>	Many Ford cars now feature Microsoft's SYNC technology, providing speech-synthesis (for reading text messages to you) and speech-recognition capabilities that allow you to use voice commands to browse music, request traffic alerts and more.
AMBER <sup>™</sup> Alert	The AMBER (America's Missing: Broadcast Emergency Response) Alert System is used to find abducted children. Law enforcement notifies TV and radio broadcasters and state transportation officials, who then broadcast alerts on TV, radio, computerized highway signs, the Internet and wireless devices. AMBER Alert recently partnered with Facebook. Facebook users can "Like" AMBER Alert pages by location to receive alerts in their news feeds.
Robots	Robots are computerized machines that can perform tasks (including physical tasks), respond to stimuli and more. They can be used for day-to-day tasks (e.g., iRobot's Roomba vacuum), entertainment (such as robotic pets), military combat, space and deep sea exploration, manufacturing and more. In 2004, NASA's remote-controlled Mars rover—which used Java technology—explored the surface to learn about the history of water on the planet.

**Fig. 1.1** | A few uses for computers. (Part 2 of 3.)

Name	Description
One Laptop Per Child (OLPC)	One Laptop Per Child (OLPC) is providing low-power, inexpensive, Internet-enabled laptops to poor children worldwide—enabling learning and reducing the digital divide ( <a href="http://one.laptop.org">one.laptop.org</a> ). By providing these educational resources, OLPC is increasing the opportunities for poor children to learn and make a difference in their communities.
Game programming	The computer game business is larger than the first-run movie business. The most sophisticated video games can cost as much as \$100 million to develop. Activision's <i>Call of Duty 2: Modern Warfare</i> , released in November 2009, earned \$310 million in just one day in North America and the U.K. ( <a href="http://news.cnet.com/8301-13772_3-10396593-52.html?tag=mncol;txt">news.cnet.com/8301-13772_3-10396593-52.html?tag=mncol;txt</a> )! Online <i>social gaming</i> , which enables users worldwide to compete with one another, is growing rapidly. Zynga—creator of popular online games such as <i>Farmville</i> and <i>Mafia Wars</i> —was founded in 2007 and already has over 215 million monthly users. To accommodate the growth in traffic, Zynga is adding nearly 1,000 servers each week ( <a href="http://techcrunch.com/2010/09/22/zynga-moves-1-petabyte-of-data-daily-adds-1000-servers-a-week/">techcrunch.com/2010/09/22/zynga-moves-1-petabyte-of-data-daily-adds-1000-servers-a-week/</a> )! Video game consoles are also becoming increasingly sophisticated. The Wii Remote uses an <i>accelerometer</i> (to detect tilt and acceleration) and a sensor that determines where the device is pointing, allowing the device to respond to motion. By gesturing with the Wii Remote in hand, you can control the video game on the screen. With Microsoft's Kinect for Xbox 360, you—the player—become the controller. Kinect uses a camera, depth sensor and sophisticated software to follow your body movement, allowing you to control the game ( <a href="http://en.wikipedia.org/wiki/Kinect">en.wikipedia.org/wiki/Kinect</a> ). Kinect games include dancing, exercising, playing sports, training virtual animals and more.
Internet TV	Internet TV set-top boxes (such as Apple TV and Google TV) give you access to content—such as games, news, movies, television shows and more—allowing you to access an enormous amount of content on demand; you no longer need to rely on cable or satellite television providers to get content.

**Fig. 1.1** | A few uses for computers. (Part 3 of 3.)

## 1.2 Computers: Hardware and Software

A computer is a device that can perform computations and make logical decisions phenomenally faster than human beings can. Many of today's personal computers can perform billions of calculations in one second—more than a human can perform in a lifetime. *Supercomputers* are already performing *thousands of trillions (quadrillions)* of instructions per second! To put that in perspective, a quadrillion-instruction-per-second computer can perform in one second more than 100,000 calculations *for every person on the planet!* And—these “upper limits” are growing quickly!

Computers process data under the control of sets of instructions called **computer programs**. These programs guide the computer through orderly sets of actions specified by people called computer **programmers**. The programs that run on a computer are referred to as **software**. In this book, you'll learn today's key programming methodology that's enhancing programmer productivity, thereby reducing software-development costs—*object-oriented programming*.

A computer consists of various devices referred to as **hardware** (e.g., the keyboard, screen, mouse, hard disks, memory, DVDs and processing units). Computing costs are *dropping dramatically*, owing to rapid developments in hardware and software technologies. Computers that might have filled large rooms and cost millions of dollars decades ago are now inscribed on silicon chips smaller than a fingernail, costing perhaps a few dollars each. Ironically, silicon is one of the most abundant materials—it's an ingredient in common sand. Silicon-chip technology has made computing so economical that more than a billion general-purpose computers are in use worldwide, and this is expected to *double* in the next few years.

Computer chips (*microprocessors*) control countless devices. These **embedded systems** include anti-lock brakes in cars, navigation systems, smart home appliances, home security systems, cell phones and smartphones, robots, intelligent traffic intersections, collision avoidance systems, video game controllers and more. The vast majority of the microprocessors produced each year are embedded in devices other than general-purpose computers.<sup>6</sup>

### Moore's Law

Every year, you probably expect to pay at least a little more for most products and services. The opposite has been the case in the computer and communications fields, especially with regard to the costs of hardware supporting these technologies. For many decades, hardware costs have fallen rapidly. Every year or two, the capacities of computers have approximately *doubled* without any increase in price. This remarkable observation often is called **Moore's Law**, named for the person who identified the trend, Gordon Moore, co-founder of Intel—a leading manufacturer of the processors in today's computers and embedded systems. Moore's Law and related observations are especially true in relation to the amount of memory that computers have for programs, the amount of secondary storage (such as disk storage) they have to hold programs and data over longer periods of time, and their processor speeds—the speeds at which computers execute their programs (i.e., do their work). Similar growth has occurred in the communications field, in which costs have plummeted as enormous demand for communications bandwidth (i.e., information-carrying capacity) has attracted intense competition. We know of no other fields in which technology improves so quickly and costs fall so rapidly. Such phenomenal improvement is truly fostering the *Information Revolution*.

## 1.3 Data Hierarchy

Data items processed by computers form a **data hierarchy** that becomes larger and more complex in structure as we progress from bits to characters to fields, and so on. Figure 1.2 illustrates a portion of the data hierarchy. Figure 1.3 summarizes the data hierarchy's levels.

6. [www.eetimes.com/electronics-blogs/industrial-control-designline-blog/4027479/Real-men-program-in-C?pageNumber=1](http://www.eetimes.com/electronics-blogs/industrial-control-designline-blog/4027479/Real-men-program-in-C?pageNumber=1).

**Fig. I.2** | Data hierarchy.

Level	Description
Bits	The smallest data item in a computer can assume the value 0 or the value 1. Such a data item is called a <b>bit</b> (short for “binary digit”—a digit that can assume one of two values). It’s remarkable that the impressive functions performed by computers involve only the simplest manipulations of 0s and 1s— <i>examining a bit’s value</i> , <i>setting a bit’s value</i> and <i>reversing a bit’s value</i> (from 1 to 0 or from 0 to 1).
Characters	It’s tedious for people to work with data in the low-level form of bits. Instead, they prefer to work with <i>decimal digits</i> (0–9), <i>letters</i> (A–Z and a–z), and <i>special symbols</i> (e.g., \$, @, %, &, *, (, ), -, +, ", :, ? and /). Digits, letters and special symbols are known as <b>characters</b> . The computer’s <b>character set</b> is the set of all the characters used to write programs and represent data items. Computers process only 1s and 0s, so a computer’s character set represents every character as a pattern of 1s and 0s. Java uses <b>Unicode</b> <sup>®</sup> characters that are composed of two <b>bytes</b> , each composed of eight bits. Unicode contains characters for many of the world’s languages. See Appendix L for more information on Unicode. See Appendix B for more information on the <b>ASCII (American Standard Code for Information Interchange)</b> character set—the popular subset of Unicode that represents uppercase and lowercase letters, digits and some common special characters.

**Fig. I.3** | Levels of the data hierarchy. (Part 1 of 2.)

Level	Description
Fields	Just as characters are composed of bits, <b>fields</b> are composed of characters or bytes. A field is a group of characters or bytes that conveys meaning. For example, a field consisting of uppercase and lowercase letters can be used to represent a person's name, and a field consisting of decimal digits could represent a person's age.
Records	Several related fields can be used to compose a <b>record</b> (implemented as a <code>class</code> in Java). In a payroll system, for example, the record for an employee might consist of the following fields (possible types for these fields are shown in parentheses): <ul style="list-style-type: none"> <li>• Employee identification number (a whole number)</li> <li>• Name (a string of characters)</li> <li>• Address (a string of characters)</li> <li>• Hourly pay rate (a number with a decimal point)</li> <li>• Year-to-date earnings (a number with a decimal point)</li> <li>• Amount of taxes withheld (a number with a decimal point)</li> </ul> <p>Thus, a record is a group of related fields. In the preceding example, all the fields belong to the same employee. A company might have many employees and a payroll record for each one.</p>
Files	A <b>file</b> is a group of related records. [ <i>Note:</i> More generally, a file contains arbitrary data in arbitrary formats. In some operating systems, a file is viewed simply as a <i>sequence of bytes</i> —any organization of the bytes in a file, such as organizing the data into records, is a view created by the application programmer.] It's not unusual for an organization to have many files, some containing billions, or even trillions, of characters of information.

**Fig. 1.3** | Levels of the data hierarchy. (Part 2 of 2.)

## 1.4 Computer Organization

Regardless of differences in physical appearance, computers can be envisioned as divided into various **logical units** or sections (Fig. 1.4).

Logical unit	Description
<b>Input unit</b>	This “receiving” section obtains information (data and computer programs) from <b>input devices</b> and places it at the disposal of the other units for processing. Most information is entered into computers through keyboards, touch screens and mouse devices. Other forms of input include speaking to your computer, scanning images and barcodes, reading from secondary storage devices (like hard drives, DVD drives, Blu-ray Disc™ drives and USB flash drives—also called “thumb drives” or “memory sticks”), receiving video from a webcam and having your computer receive information from the Internet (such as when you download videos from YouTube™ or e-books from Amazon). Newer forms of input include reading position data from a GPS device, and motion and orientation information from an accelerometer in a smartphone or game controller.

**Fig. 1.4** | Logical units of a computer. (Part 1 of 2.)

Logical unit	Description
<b>Output unit</b>	This “shipping” section takes information that the computer has processed and places it on various <b>output devices</b> to make it available for use outside the computer. Most information that’s output from computers today is displayed on screens, printed on paper, played as audio or video on portable media players (such as Apple’s popular iPods) and giant screens in sports stadiums, transmitted over the Internet or used to control other devices, such as robots and “intelligent” appliances.
<b>Memory unit</b>	This rapid-access, relatively low-capacity “warehouse” section retains information that has been entered through the input unit, making it immediately available for processing when needed. The memory unit also retains processed information until it can be placed on output devices by the output unit. Information in the memory unit is <i>volatile</i> —it’s typically lost when the computer’s power is turned off. The memory unit is often called either <b>memory</b> or <b>primary memory</b> . Typical main memories on desktop and notebook computers contain between 1 GB and 8 GB (GB stands for gigabytes; a gigabyte is approximately one billion bytes).
<b>Arithmetic and logic unit (ALU)</b>	This “manufacturing” section performs <i>calculations</i> , such as addition, subtraction, multiplication and division. It also contains the <i>decision</i> mechanisms that allow the computer, for example, to compare two items from the memory unit to determine whether they’re equal. In today’s systems, the ALU is usually implemented as part of the next logical unit, the CPU.
<b>Central processing unit (CPU)</b>	This “administrative” section coordinates and supervises the operation of the other sections. The CPU tells the input unit when information should be read into the memory unit, tells the ALU when information from the memory unit should be used in calculations and tells the output unit when to send information from the memory unit to certain output devices. Many of today’s computers have multiple CPUs and, hence, can perform many operations simultaneously. A <b>multi-core processor</b> implements multiple processors on a single integrated-circuit chip—a <i>dual-core processor</i> has two CPUs and a <i>quad-core processor</i> has four CPUs. Today’s desktop computers have processors that can execute billions of instructions per second.
<b>Secondary storage unit</b>	This is the long-term, high-capacity “warehousing” section. Programs or data not actively being used by the other units normally are placed on secondary storage devices (e.g., your <i>hard drive</i> ) until they’re again needed, possibly hours, days, months or even years later. Information on secondary storage devices is <i>persistent</i> —it’s preserved even when the computer’s power is turned off. Secondary storage information takes much longer to access than information in primary memory, but the cost per unit of secondary storage is much less than that of primary memory. Examples of secondary storage devices include CD drives, DVD drives and flash drives, some of which can hold up to 128 GB. Typical hard drives on desktop and notebook computers can hold up to 2 TB (TB stands for terabytes; a terabyte is approximately one trillion bytes).

**Fig. I.4** | Logical units of a computer. (Part 2 of 2.)

## 1.5 Machine Languages, Assembly Languages and High-Level Languages

Programmers write instructions in various programming languages, some directly understandable by computers and others requiring intermediate *translation* steps. Hundreds of such languages are in use today. These may be divided into three general types:

1. Machine languages
2. Assembly languages
3. High-level languages

Any computer can directly understand only its own **machine language**, defined by its hardware design. Machine languages generally consist of strings of numbers (ultimately reduced to 1s and 0s) that instruct computers to perform their most elementary operations one at a time. Machine languages are *machine dependent* (a particular machine language can be used on only one type of computer). Such languages are cumbersome for humans. For example, here's a section of an early machine-language program that adds overtime pay to base pay and stores the result in gross pay:

```
+1300042774
+1400593419
+1200274027
```

Programming in machine language was simply too slow and tedious for most programmers. Instead of using the strings of numbers that computers could directly understand, programmers began using English-like abbreviations to represent elementary operations. These abbreviations formed the basis of **assembly languages**. *Translator programs* called **assemblers** were developed to convert early assembly-language programs to machine language at computer speeds. The following section of an assembly-language program also adds overtime pay to base pay and stores the result in gross pay:

```
load    basepay
add     overpay
store  grosspay
```

Although such code is clearer to humans, it's incomprehensible to computers until translated to machine language.

Computer usage increased rapidly with the advent of assembly languages, but programmers still had to use many instructions to accomplish even the simplest tasks. To speed the programming process, **high-level languages** were developed in which single statements could be written to accomplish substantial tasks. Translator programs called **compilers** convert high-level language programs into machine language. High-level languages allow you to write instructions that look almost like everyday English and contain commonly used mathematical notations. A payroll program written in a high-level language might contain a *single* statement such as

```
grossPay = basePay + overTimePay
```

From the programmer's standpoint, high-level languages are preferable to machine and assembly languages. Java is by far the most widely used high-level programming language.

Compiling a large high-level language program into machine language can take a considerable amount of computer time. *Interpreter* programs were developed to execute high-level language programs directly (without the delay of compilation), although slower than compiled programs run. We'll say more about how interpreters work in Section 1.9, where you'll learn that Java uses a clever performance-tuned mixture of compilation and interpretation to ultimately run programs. Exercises 7.35–7.37 (in the Special Section: Building Your Own Computer) guide you through the process of building an interpreter program.

## 1.6 Introduction to Object Technology

Building software quickly, correctly and economically remains an elusive goal at a time when demands for new and more powerful software are soaring. *Objects*, or more precisely—as we'll see in Chapter 3—the *classes* objects come from, are essentially *reusable* software components. There are date objects, time objects, audio objects, video objects, automobile objects, people objects, etc. Almost any *noun* can be reasonably represented as a software object in terms of *attributes* (e.g., name, color and size) and *behaviors* (e.g., calculating, moving and communicating). Software developers are discovering that using a modular, object-oriented design and implementation approach can make software-development groups much more productive than was possible with earlier popular techniques like “structured programming”—object-oriented programs are often easier to understand, correct and modify.

### *The Automobile as an Object*

To help you understand objects and their contents, let's begin with a simple analogy. Suppose you want to *drive a car and make it go faster by pressing its accelerator pedal*. What must happen before you can do this? Well, before you can drive a car, someone has to *design* it. A car typically begins as engineering drawings, similar to the *blueprints* that describe the design of a house. These drawings include the design for an accelerator pedal. The pedal *hides* from the driver the complex mechanisms that actually make the car go faster, just as the brake pedal hides the mechanisms that slow the car, and the steering wheel “hides” the mechanisms that turn the car. This enables people with little or no knowledge of how engines, braking and steering mechanisms work to drive a car easily.

Just as you cannot cook meals in the kitchen of a blueprint, you cannot drive a car's engineering drawings. Before you can drive a car, it must be *built* from the engineering drawings that describe it. A completed car has an *actual* accelerator pedal to make the car go faster, but even that's not enough—the car won't accelerate on its own (hopefully!), so the driver must *press* the pedal to accelerate the car.

### *Methods and Classes*

Let's use our car example to introduce some key object-oriented programming concepts. Performing a task in a program requires a **method**. The method houses the program statements that actually perform its tasks. The method hides these statements from its user, just as the accelerator pedal of a car hides from the driver the mechanisms of making the car go faster. In Java, we create a program unit called a **class** to house the set of methods that

perform the class's tasks. For example, a class that represents a bank account might contain one method to *deposit* money to an account, another to *withdraw* money from an account and a third to *inquire* what the account's current balance is. A class is similar in concept to a car's engineering drawings, which house the design of an accelerator pedal, steering wheel, and so on.

### Instantiation

Just as someone has to *build a car* from its engineering drawings before you can actually drive a car, you must *build an object* of a class before a program can perform the tasks that the class's methods define. The process of doing this is called *instantiation*. An object is then referred to as an **instance** of its class.

### Reuse

Just as a car's engineering drawings can be *reused* many times to build many cars, you can *reuse* a class many times to build many objects. Reuse of existing classes when building new classes and programs saves time and effort. Reuse also helps you build more reliable and effective systems, because existing classes and components often have gone through extensive *testing*, *debugging* and *performance* tuning. Just as the notion of *interchangeable parts* was crucial to the Industrial Revolution, reusable classes are crucial to the software revolution that has been spurred by object technology.

### Software Engineering Observation 1.1

*Use a building-block approach to creating your programs. Avoid reinventing the wheel—use existing pieces wherever possible. This software reuse is a key benefit of object-oriented programming.*

### Messages and Methods Calls

When you drive a car, pressing its gas pedal sends a *message* to the car to perform a task—that is, to go faster. Similarly, you *send messages to an object*. Each message is implemented as a **method call** that tells a method of the object to perform its task. For example, a program might call a particular bank account object's *deposit* method to increase the account's balance.

### Attributes and Instance Variables

A car, besides having capabilities to accomplish tasks, also has *attributes*, such as its color, its number of doors, the amount of gas in its tank, its current speed and its record of total miles driven (i.e., its odometer reading). Like its capabilities, the car's attributes are represented as part of its design in its engineering diagrams (which, for example, include an odometer and a fuel gauge). As you drive an actual car, these attributes are carried along with the car. Every car maintains its *own* attributes. For example, each car knows how much gas is in its own gas tank, but *not* how much is in the tanks of *other* cars.

An object, similarly, has attributes that it carries along as it's used in a program. These attributes are specified as part of the object's class. For example, a bank account object has a *balance attribute* that represents the amount of money in the account. Each bank account object knows the balance in the account it represents, but *not* the balances of the *other* accounts in the bank. Attributes are specified by the class's **instance variables**.

### *Encapsulation*

Classes **encapsulate** (i.e., wrap) attributes and methods into objects—an object’s attributes and methods are intimately related. Objects may communicate with one another, but they’re normally not allowed to know how other objects are implemented—implementation details are *hidden* within the objects themselves. This **information hiding**, as we’ll see, is crucial to good software engineering.

### *Inheritance*

A new class of objects can be created quickly and conveniently by **inheritance**—the new class absorbs the characteristics of an existing class, possibly customizing them and adding unique characteristics of its own. In our car analogy, an object of class “convertible” certainly *is an* object of the more *general* class “automobile,” but more *specifically*, the roof can be raised or lowered.

### *Object-Oriented Analysis and Design (OOAD)*

Soon you’ll be writing programs in Java. How will you create the **code** (i.e., the program instructions) for your programs? Perhaps, like many programmers, you’ll simply turn on your computer and start typing. This approach may work for small programs (like the ones we present in the early chapters of the book), but what if you were asked to create a software system to control thousands of automated teller machines for a major bank? Or suppose you were asked to work on a team of 1,000 software developers building the next U.S. air traffic control system? For projects so large and complex, you should not simply sit down and start writing programs.

To create the best solutions, you should follow a detailed **analysis** process for determining your project’s **requirements** (i.e., defining *what* the system is supposed to do) and developing a **design** that satisfies them (i.e., deciding *how* the system should do it). Ideally, you’d go through this process and carefully review the design (and have your design reviewed by other software professionals) before writing any code. If this process involves analyzing and designing your system from an object-oriented point of view, it’s called an **object-oriented analysis and design (OOAD) process**. Languages like Java are object oriented. Programming in such a language, called **object-oriented programming (OOP)**, allows you to implement an object-oriented design as a working system.

### *The UML (Unified Modeling Language)*

Although many different OOAD processes exist, a single graphical language for communicating the results of *any* OOAD process has come into wide use. This language, known as the Unified Modeling Language (UML), is now the most widely used graphical scheme for modeling object-oriented systems. We present our first UML diagrams in Chapters 3 and 4, then use them in our deeper treatment of object-oriented programming through Chapter 11. In our *optional* ATM Software Engineering Case Study in Chapters 12–13 we present a simple subset of the UML’s features as we guide you through an object-oriented design experience.

## 1.7 Operating Systems

**Operating systems** are software systems that make using computers more convenient for users, application developers and system administrators. Operating systems provide services

that allow each application to execute safely, efficiently and *concurrently* (i.e., in parallel) with other applications. The software that contains the core components of the operating system is called the **kernel**. Popular desktop operating systems include Linux, Windows 7 and Mac OS X. Popular mobile operating systems used in smartphones and tablets include Google's Android, BlackBerry OS and Apple's iOS (for its iPhone, iPad and iPod Touch devices).

### *Windows—A Proprietary Operating System*

In the mid-1980s, Microsoft developed the **Windows operating system**, consisting of a graphical user interface built on top of DOS—an enormously popular personal-computer operating system of the time that users interacted with by typing commands. Windows borrowed from many concepts (such as icons, menus and windows) popularized by early Apple Macintosh operating systems and originally developed by Xerox PARC. Windows 7 is Microsoft's latest operating system—its features include enhancements to the user interface, faster startup times, further refinement of security features, touch-screen and multi-touch support, and more. Windows is a *proprietary* operating system—it's controlled by one company exclusively. Windows is by far the world's most widely used operating system.

### *Linux—An Open-Source Operating System*

The Linux operating system is perhaps the greatest success of the *open-source* movement. **Open-source software** is a software development style that departs from the *proprietary* development that dominated software's early years. With open-source development, individuals and companies contribute their efforts in developing, maintaining and evolving software in exchange for the right to use that software for their own purposes, typically at no charge. Open-source code is often scrutinized by a much larger audience than proprietary software, so errors often get removed faster. Open source also encourages more innovation. Sun open sourced its implementation of the Java Development Kit and many of its related Java technologies.

Some organizations in the open-source community are the Eclipse Foundation (the Eclipse Integrated Development Environment helps Java programmers conveniently develop software), the Mozilla Foundation (creators of the Firefox web browser), the Apache Software Foundation (creators of the Apache web server used to develop web-based applications) and SourceForge (which provides the tools for managing open source projects—it has over 260,000 of them under development). Rapid improvements to computing and communications, decreasing costs and open-source software have made it much easier and more economical to create a software-based business now than just a few decades ago. A great example is Facebook, which was launched from a college dorm room and built with open-source software.<sup>7</sup>

The **Linux** kernel is the core of the most popular open-source, freely distributed, full-featured operating system. It's developed by a loosely organized team of volunteers, and is popular in servers, personal computers and embedded systems. Unlike that of proprietary operating systems like Microsoft's Windows and Apple's Mac OS X, Linux source code (the program code) is available to the public for examination and modification and is free to download and install. As a result, users of the operating system benefit from a community of developers actively debugging and improving the kernel, an absence of licensing

---

7. [developers.facebook.com/opensource/](http://developers.facebook.com/opensource/).

fees and restrictions, and the ability to completely customize the operating system to meet specific needs.

In 1991, Linus Torvalds, a 21-year-old student at the University of Helsinki, Finland, began developing the Linux kernel as a hobby. (The name Linux is derived from “Linus” and “UNIX”—an operating system developed by Bell Labs in 1969.) Torvalds wished to improve upon the design of Minix, an educational operating system created by Professor Andrew Tanenbaum of the Vrije Universiteit in Amsterdam. The Minix source code was publicly available to allow professors to demonstrate basic operating-system implementation concepts to their students.

Torvalds released the first version of Linux in 1991. The favorable response led to the creation of a community that has continued to develop and support Linux. Developers downloaded, tested, and modified the Linux code, submitting bug fixes and feedback to Torvalds, who reviewed them and applied the improvements to the code.

The 1994 release of Linux included many features commonly found in a mature operating system, making Linux a viable alternative to UNIX. Enterprise systems companies such as IBM and Oracle became increasingly interested in Linux as it continued to stabilize and spread to new platforms.

A variety of issues—such as Microsoft’s market power, the small number of user-friendly Linux applications and the diversity of Linux distributions, such as Red Hat Linux, Ubuntu Linux and many others—have prevented widespread Linux use on desktop computers. But Linux has become extremely popular on servers and in embedded systems, such as Google’s Android-based smartphones.

### *Android*

**Android**—the fastest growing mobile and smartphone operating system—is based on the Linux kernel and Java. Experienced Java programmers can quickly dive into Android development. One benefit of developing Android apps is the openness of the platform. The operating system is open source and free.

The Android operating system was developed by Android, Inc., which was acquired by Google in 2005. In 2007, the Open Handset Alliance™—a consortium of 34 companies initially and 79 by 2010—was formed to continue developing Android. As of December 2010, more than 300,000 Android smartphones were being activated each day!<sup>8</sup> Android smartphones are now outselling iPhones.<sup>9</sup> The Android operating system is used in numerous smartphones (such as the Motorola Droid, HTC EVO™ 4G, Samsung Vibrant™ and many more), e-reader devices (such as the Barnes and Noble Nook™), tablet computers (such as the Dell Streak, the Samsung Galaxy Tab and more), in-store touch-screen kiosks, cars, robots and multimedia players.

Android smartphones include the functionality of a mobile phone, Internet client (for web browsing and Internet communication), MP3 player, gaming console, digital camera and more, wrapped into handheld devices with full-color *multitouch screens*—these allow you to control the device with *gestures* involving one touch or multiple simultaneous touches. You can download apps directly onto your Android device through Android Market and other app marketplaces. As of December 2010, there were over 200,000 apps in Google’s Android Market.

### *Android App-Development Chapters on the Companion Website*

Because of the tremendous interest in Android-based devices and apps, we've included on the book's companion website a three-chapter introduction to Android app development from our new book, *Android for Programmers: An App-Driven Approach*. After you learn Java, you'll find it straightforward to begin developing and running Android apps. You can place your apps on the online Android Market ([www.market.android.com](http://www.market.android.com)) and if they're successful, you may even be able to launch a business. Just remember—Facebook, Microsoft and Dell were all launched from dorm rooms.

## 1.8 Programming Languages

In this section, we provide brief comments on several popular programming languages (Fig. 1.5). In the next section we introduce Java.

Programming language	Description
Fortran	Fortran (FORMula TRANslator) was developed by IBM Corporation in the mid-1950s to be used for scientific and engineering applications that require complex mathematical computations. It's still widely used and its latest versions are object oriented.
COBOL	COBOL (COMmon Business Oriented Language) was developed in the late 1950s by computer manufacturers, the U.S. government and industrial computer users based on a language developed by Grace Hopper, a career U.S. Navy officer and computer scientist. COBOL is still widely used for commercial applications that require precise and efficient manipulation of large amounts of data. Its latest version supports object-oriented programming.
Pascal	Research in the 1960s resulted in <i>structured programming</i> —a disciplined approach to writing programs that are clearer, easier to test and debug and easier to modify than large programs produced with previous techniques. One of the more tangible results of this research was the development of Pascal by Professor Niklaus Wirth in 1971. It was designed for teaching structured programming and was popular in college courses for several decades.
Ada	Ada, based on Pascal, was developed under the sponsorship of the U.S. Department of Defense (DOD) during the 1970s and early 1980s. The DOD wanted a single language that would fill most of its needs. The Pascal-based language was named after Lady Ada Lovelace, daughter of the poet Lord Byron. She's credited with writing the world's first computer program in the early 1800s (for the Analytical Engine mechanical computing device designed by Charles Babbage). Its latest version supports object-oriented programming.
Basic	Basic was developed in the 1960s at Dartmouth College to introduce novices to programming. Many of its latest versions are object oriented.
C	C was implemented in 1972 by Dennis Ritchie at Bell Laboratories. It initially became widely known as the UNIX operating system's development language. Today, most of the code for general-purpose operating systems is written in C or C++.

**Fig. 1.5** | Other programming languages. (Part 1 of 2.)

Programming language	Description
C++	C++, an extension of C, was developed by Bjarne Stroustrup in the early 1980s at Bell Laboratories. C++ provides a number of features that “spruce up” the C language, but more important, it provides capabilities for object-oriented programming.
Objective-C	Objective-C is an object-oriented language based on C. It was developed in the early 1980s and later acquired by Next, which in turn was acquired by Apple. It has become the key programming language for the Mac OS X operating system and all iOS-powered devices (such as iPods, iPhones and iPads).
Visual Basic	Microsoft’s Visual Basic language was introduced in the early 1990s to simplify the development of Microsoft Windows applications. Its latest versions support object-oriented programming.
Visual C#	Microsoft’s three primary object-oriented programming languages are Visual Basic, Visual C++ (based on C++) and C# (based on C++ and Java, and developed for integrating the Internet and the web into computer applications).
PHP	PHP is an object-oriented, “open-source” (see Section 1.7) “scripting” language supported by a community of users and developers and is used by numerous websites including Wikipedia and Facebook. PHP is platform independent—implementations exist for all major UNIX, Linux, Mac and Windows operating systems. PHP also supports many databases, including MySQL.
Python	Python, another object-oriented scripting language, was released publicly in 1991. Developed by Guido van Rossum of the National Research Institute for Mathematics and Computer Science in Amsterdam (CWI), Python draws heavily from Modula-3—a systems programming language. Python is “extendible”—it can be extended through classes and programming interfaces.
JavaScript	JavaScript is the most widely used scripting language. It’s primarily used to add programmability to web pages—for example, animations and interactivity with the user. It’s provided with all major web browsers.
Ruby on Rails	Ruby—created in the mid-1990s by Yukihiro Matsumoto—is an open-source, object-oriented programming language with a simple syntax that’s similar to Python. Ruby on Rails combines the scripting language Ruby with the Rails web application framework developed by 37Signals. Their book, <i>Getting Real</i> ( <a href="http://gettingreal.37signals.com/toc.php">gettingreal.37signals.com/toc.php</a> ), is a must read for web developers. Many Ruby on Rails developers have reported productivity gains over other languages when developing database-intensive web applications. Ruby on Rails was used to build Twitter’s user interface.
Scala	Scala ( <a href="http://www.scala-lang.org/node/273">www.scala-lang.org/node/273</a> )—short for “scalable language”—was designed by Martin Odersky, a professor at École Polytechnique Fédérale de Lausanne (EPFL) in Switzerland. Released in 2003, Scala uses both the object-oriented and functional programming paradigms and is designed to integrate with Java. Programming in Scala can reduce the amount of code in your applications significantly. Twitter and Foursquare use Scala.

**Fig. 1.5** | Other programming languages. (Part 2 of 2.)

## 1.9 Java and a Typical Java Development Environment

The microprocessor revolution's most important contribution to date is that it made possible the development of personal computers. Microprocessors are having a profound impact in intelligent consumer-electronic devices. Recognizing this, Sun Microsystems in 1991 funded an internal corporate research project led by James Gosling, which resulted in a C++-based object-oriented programming language Sun called Java.

A key goal of Java is to be able to write programs that will run on a great variety of computer systems and computer-control devices. This is sometimes called “write once, run anywhere.”

The web exploded in popularity in 1993, and Sun saw the potential of using Java to add *dynamic content*, such as interactivity and animations, to web pages. Java garnered the attention of the business community because of the phenomenal interest in the web. Java is now used to develop large-scale enterprise applications, to enhance the functionality of web servers (the computers that provide the content we see in our web browsers), to provide applications for consumer devices (e.g., cell phones, smartphones, television set-top boxes and more) and for many other purposes. Sun Microsystems was acquired by Oracle in 2009. At the JavaOne 2010 conference, Oracle announced that 97% of enterprise desktops, three billion handsets, and 80 million television devices run Java. There are currently over 9 million Java developers, up from 4.5 million in 2005.<sup>10</sup> Java is now the most widely used software development language in the world.

### Java Class Libraries

You can create each class and method you need to form your Java programs. However, most Java programmers take advantage of the rich collections of existing classes and methods in the **Java class libraries**, which are also known as the **Java APIs (Application Programming Interfaces)**.

#### Performance Tip 1.1

*Using Java API classes and methods instead of writing your own versions can improve program performance, because they're carefully written to perform efficiently. This also shortens program development time.*

#### Portability Tip 1.1

*Although it's easier to write portable programs (i.e., programs that can run on many different types of computers) in Java than in most other programming languages, differences between compilers, JVMs and computers can make portability difficult to achieve. Simply writing programs in Java does not guarantee portability.*

We now explain the commonly used steps in creating and executing a Java application using a Java development environment (illustrated in Figs. 1.6–1.10). Java programs normally go through five phases—edit, compile, load, verify and execute. We discuss these phases in the context of the Java SE Development Kit (JDK). You can download the most up-to-date JDK and its documentation from [www.oracle.com/technetwork/java/](http://www.oracle.com/technetwork/java/)

10. [jaxenter.com/how-many-java-developers-are-there-10462.html](http://jaxenter.com/how-many-java-developers-are-there-10462.html).

javase/downloads/index.html. Read the *Before You Begin* section of this book to ensure that you set up your computer properly to compile and execute Java programs. You may also want to visit Oracle’s New to Java Center at:

[www.oracle.com/technetwork/topics/newtojava/overview/index.html](http://www.oracle.com/technetwork/topics/newtojava/overview/index.html)

[*Note:* This website provides installation instructions for Windows, Linux and Mac OS X. If you aren’t using one of these operating systems, refer to the documentation for your system’s Java environment or ask your instructor how to accomplish these tasks based on your computer’s operating system. If you encounter a problem with this link or any others referenced in this book, please check [www.deitel.com/books/jhttp9/](http://www.deitel.com/books/jhttp9/) for errata and please notify us by e-mail at [deitel@deitel.com](mailto:deitel@deitel.com).]

### Phase 1: Creating a Program

Phase 1 consists of editing a file with an *editor program*, normally known simply as an *editor* (Fig. 1.6). You type a Java program (typically referred to as **source code**) using the editor, make any necessary corrections and save the program on a secondary storage device, such as your hard drive. A file name ending with the **.java extension** indicates that the file contains Java source code.

**Fig. 1.6** | Typical Java development environment—editing phase.

Two editors widely used on Linux systems are *vi* and *emacs*. On Windows, Notepad will suffice. Many freeware and shareware editors are also available online, including Edit-Plus ([www.ediplus.com](http://www.ediplus.com)), TextPad ([www.textpad.com](http://www.textpad.com)) and jEdit ([www.jedit.org](http://www.jedit.org)).

For organizations that develop substantial information systems, **integrated development environments (IDEs)** are available from many major software suppliers. IDEs provide tools that support the software development process, including editors for writing and editing programs and debuggers for locating **logic errors**—errors that cause programs to execute incorrectly. Popular IDEs include Eclipse ([www.eclipse.org](http://www.eclipse.org)) and NetBeans ([www.netbeans.org](http://www.netbeans.org)).

### Phase 2: Compiling a Java Program into Bytecodes

In Phase 2, you use the command **javac** (the **Java compiler**) to **compile** a program (Fig. 1.7). For example, to compile a program called `Welcome.java`, you’d type

```
javac Welcome.java
```

in the command window of your system (i.e., the **Command Prompt** in Windows, the *shell prompt* in Linux or the Terminal application in Mac OS X). If the program compiles, the compiler produces a **.class** file called `Welcome.class` that contains the compiled version of the program.

**Fig. 1.7** | Typical Java development environment—compilation phase.

The Java compiler translates Java source code into **bytecodes** that represent the tasks to execute in the execution phase (Phase 5). Bytecodes are executed by the **Java Virtual Machine (JVM)**—a part of the JDK and the foundation of the Java platform. A **virtual machine (VM)** is a software application that simulates a computer but hides the underlying operating system and hardware from the programs that interact with it. If the same VM is implemented on many computer platforms, applications that it executes can be used on all those platforms. The JVM is one of the most widely used virtual machines. Microsoft’s .NET uses a similar virtual-machine architecture.

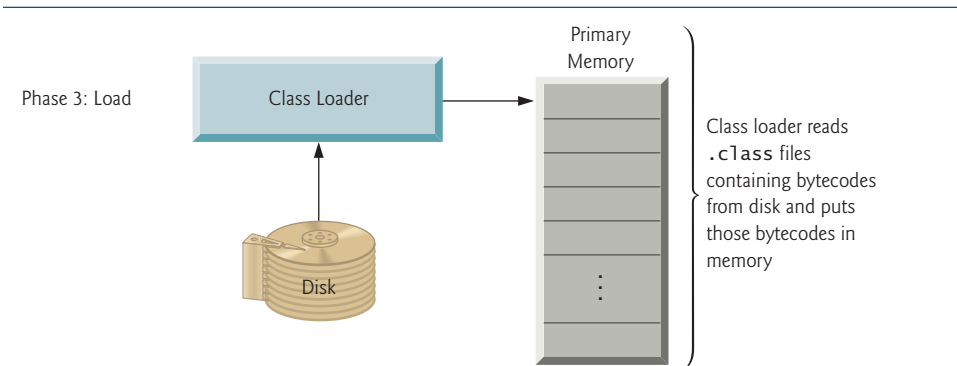

Unlike machine language, which is dependent on specific computer hardware, bytecodes are platform independent—they do not depend on a particular hardware platform. So, Java’s bytecodes are **portable**—without recompiling the source code, the same bytecodes can execute on any platform containing a JVM that understands the version of Java in which the bytecodes were compiled. The JVM is invoked by the **java** command. For example, to execute a Java application called `Welcome`, you’d type the command

```
java Welcome
```

in a command window to invoke the JVM, which would then initiate the steps necessary to execute the application. This begins Phase 3.

### *Phase 3: Loading a Program into Memory*

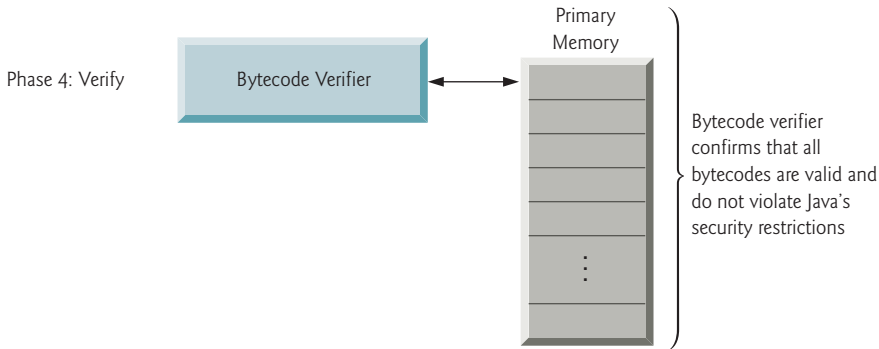

In Phase 3, the JVM places the program in memory to execute it—this is known as **loading** (Fig. 1.8). The JVM’s **class loader** takes the `.class` files containing the program’s bytecodes and transfers them to primary memory. The class loader also loads any of the `.class` files provided by Java that your program uses. The `.class` files can be loaded from a disk on your system or over a network (e.g., your local college or company network, or the Internet).

**Fig. 1.8** | Typical Java development environment—loading phase.

**Phase 4: Bytecode Verification**

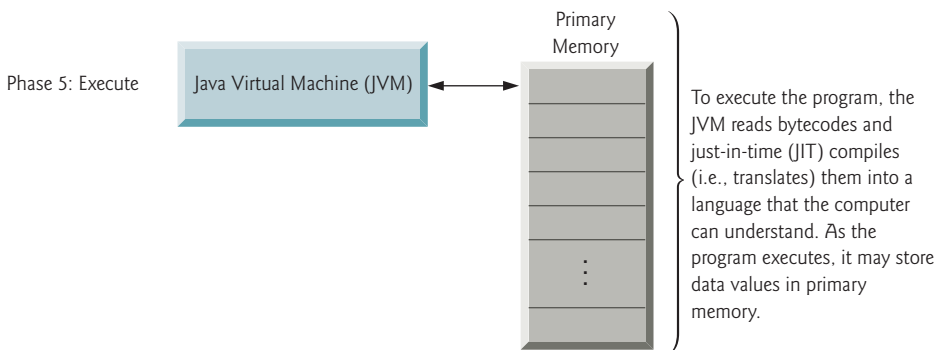

In Phase 4, as the classes are loaded, the **bytecode verifier** examines their bytecodes to ensure that they're valid and do not violate Java's security restrictions (Fig. 1.9). Java enforces strong security to make sure that Java programs arriving over the network do not damage your files or your system (as computer viruses and worms might).

**Fig. 1.9** | Typical Java development environment—verification phase.

**Phase 5: Execution**

In Phase 5, the JVM **executes** the program's bytecodes, thus performing the actions specified by the program (Fig. 1.10). In early Java versions, the JVM was simply an interpreter for Java bytecodes. This caused most Java programs to execute slowly, because the JVM would interpret and execute one bytecode at a time. Some modern computer architectures can execute several instructions in parallel. Today's JVMs typically execute bytecodes using a combination of interpretation and so-called **just-in-time (JIT) compilation**. In this process, the JVM analyzes the bytecodes as they're interpreted, searching for *hot spots*—parts of the bytecodes that execute frequently. For these parts, a **just-in-time (JIT) compiler**—known as the **Java HotSpot compiler**—translates the bytecodes into the underlying computer's machine language. When the JVM encounters these compiled parts again,

**Fig. 1.10** | Typical Java development environment—execution phase.

the faster machine-language code executes. Thus Java programs actually go through *two* compilation phases—one in which source code is translated into bytecodes (for portability across JVMs on different computer platforms) and a second in which, during execution, the bytecodes are translated into machine language for the actual computer on which the program executes.

### *Problems That May Occur at Execution Time*

Programs might not work on the first try. Each of the preceding phases can fail because of various errors that we'll discuss throughout this book. For example, an executing program might try to divide by zero (an illegal operation for whole-number arithmetic in Java). This would cause the Java program to display an error message. If this occurred, you'd have to return to the edit phase, make the necessary corrections and proceed through the remaining phases again to determine that the corrections fixed the problem(s). [*Note:* Most programs in Java input or output data. When we say that a program displays a message, we normally mean that it displays that message on your computer's screen. Messages and other data may be output to other devices, such as disks and hardcopy printers, or even to a network for transmission to other computers.]

#### **Common Programming Error 1.1**

*Errors such as division by zero occur as a program runs, so they're called **runtime errors** or **execution-time errors**. **Fatal runtime errors** cause programs to terminate immediately without having successfully performed their jobs. **Nonfatal runtime errors** allow programs to run to completion, often producing incorrect results.*

## 1.10 Test-Driving a Java Application

In this section, you'll run and interact with your first Java application. You'll begin by running an ATM application that simulates the transactions that take place when you use an ATM machine (e.g., withdrawing money, making deposits and checking your account balances). You'll learn how to build this application in the *optional*, object-oriented case study included in Chapters 12–13. For the purpose of this section, we assume you're running Microsoft Windows.<sup>11</sup>

In the following steps, you'll run the application and perform various transactions. The elements and functionality you see here are typical of what you'll learn to program in this book. [*Note:* We use fonts to distinguish between features you see on a screen (e.g., the **Command Prompt**) and elements that are not directly related to a screen. Our convention is to emphasize screen features like titles and menus (e.g., the **File** menu) in a semibold **sans-serif Helvetica** font and to emphasize nonscreen elements, such as file names or input (e.g., `ProgramName.java`) in a sans-serif **Lucida** font. As you've already noticed, the defining occurrence of each key term in the text is set in **bold maroon**. In the figures in this section, we highlight in yellow the user input required by each step and point out sig-

11. At [www.deitel.com/books/jhtp9/](http://www.deitel.com/books/jhtp9/), we provide a Linux version of this test-drive. We also provide links to videos that help you get started with several popular integrated development environments (IDEs), including Java SE Development Kit 6 for Windows, Eclipse SDK for Windows, NetBeans, jGRASP, DrJava, BlueJ and TestPad Text Editor for Windows.

nificant parts of the application. To make these features more visible, we've changed the background color of the **Command Prompt** windows to white and the foreground color to black.] This is a simple text-only version. Later in the book, you'll learn the techniques to rework this using GUI (graphical user interface) techniques.

1. *Checking your setup.* Read the Before You Begin section of the book to confirm that you've set up Java properly on your computer and that you've copied the book's examples to your hard drive.
2. *Locating the completed application.* Open a **Command Prompt** window. This can be done by selecting **Start > All Programs > Accessories > Command Prompt**. Change to the ATM application directory by typing `cd C:\examples\ch01\ATM`, then press *Enter* (Fig. 1.11). The command `cd` is used to change directories.

**Fig. 1.11** | Opening a **Command Prompt** and changing directories.

3. *Running the ATM application.* Type the command `java ATMCaseStudy` and press *Enter* (Fig. 1.12). Recall that the `java` command, followed by the name of the application's `.class` file (in this case, `ATMCaseStudy`), executes the application. Specifying the `.class` extension when using the `java` command results in an error. [*Note:* Java commands are case sensitive. It's important to type the name of this application with a capital A, T and M in "ATM," a capital C in "Case" and a capital S in "Study." Otherwise, the application will not execute.] If you receive the error message, "Exception in thread "main" java.lang.NoClassDefFoundError: ATMCaseStudy," your system has a CLASSPATH problem. Please refer to the Before You Begin section of the book for instructions to help you fix this problem.

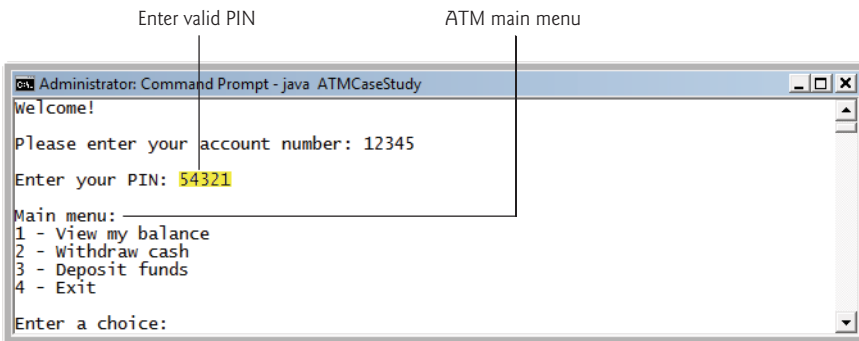

**Fig. 1.12** | Using the `java` command to execute the ATM application.

4. *Entering an account number.* When the application first executes, it displays a "Welcome!" greeting and prompts you for an account number. Type 12345 at the "Please enter your account number:" prompt (Fig. 1.13) and press *Enter*.

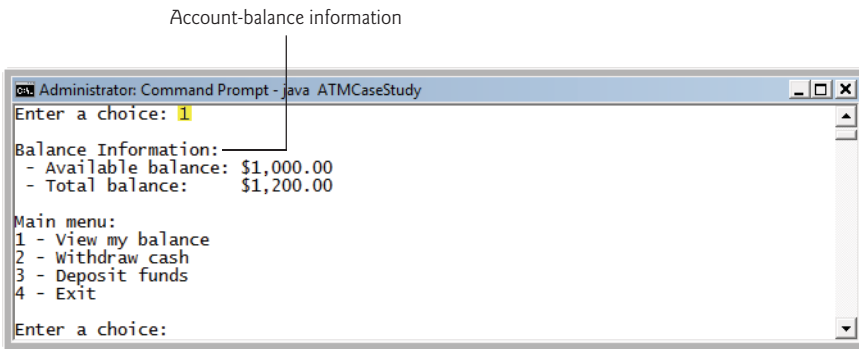

**Fig. 1.13** | Prompting the user for an account number.

5. *Entering a PIN.* Once a valid account number is entered, the application displays the prompt "Enter your PIN:". Type "54321" as your valid PIN (Personal Identification Number) and press *Enter*. The ATM main menu containing a list of options will be displayed (Fig. 1.14). We'll show how you can enter a PIN privately using a `JPasswordField` in Chapter 14.

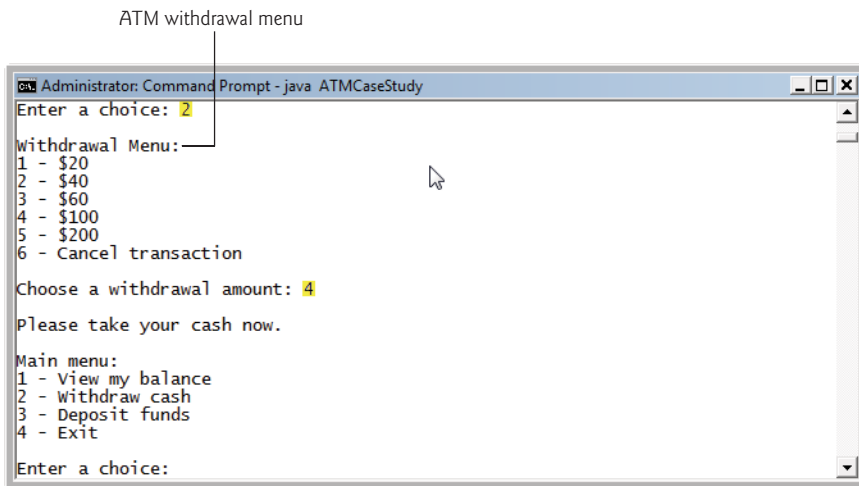

**Fig. 1.14** | Entering a valid PIN number and displaying the ATM application's main menu.

6. *Viewing the account balance.* Select option 1, "View my balance", from the ATM menu (Fig. 1.15). The application then displays two numbers—the Available balance (\$1000.00) and the Total balance (\$1200.00). The available balance is the maximum amount of money in your account which is available for withdrawal at a given time. In some cases, certain funds, such as recent deposits, are not immediately available for the user to withdraw, so the available balance may be less than the total balance, as it is here. After the account-balance information is shown, the application's main menu is displayed again.
7. *Withdrawing money from the account.* Select option 2, "Withdraw cash", from the application menu. You're then presented (Fig. 1.16) with a list of dollar amounts (e.g., 20, 40, 60, 100 and 200). You're also given the option to cancel the transaction and return to the main menu. Withdraw \$100 by selecting option 4. The application displays "Please take your cash now." and returns to the main menu. [Note: Unfortunately, this application only *simulates* the behavior of a real ATM and thus does not actually dispense money.]

**Fig. 1.15** | ATM application displaying user account-balance information.

**Fig. 1.16** | Withdrawing money from the account and returning to the main menu.

8. *Confirming that the account information has been updated.* From the main menu, select option 1 again to view your current account balance (Fig. 1.17). Both the available balance and the total balance have been updated to reflect your withdrawal transaction.
9. *Ending the transaction.* To end your current ATM session, select option 4, "Exit", from the main menu (Fig. 1.18). The ATM will exit the system and display a good-bye message to the user. The application will then return to its original prompt, asking for the next user's account number.
10. *Exiting the ATM and closing the Command Prompt window.* Most applications provide an option to exit and return to the **Command Prompt** directory from which the application was run. A real ATM does not provide a user with the option to turn off the ATM. Rather, when a user has completed all desired transactions and chosen

```
Administrator: Command Prompt - java ATMCaseStudy
Enter a choice: 1
Balance Information: _____ Confirming updated account-balance
- Available balance: $900.00      information after withdrawal transaction
- Total balance: $1,100.00
Main menu:
1 - View my balance
2 - Withdraw cash
3 - Deposit funds
4 - Exit
Enter a choice:
```

**Fig. I.17** | Checking the new balance.

```
Administrator: Command Prompt - java ATMCaseStudy
Enter a choice: 4
Exiting the system...
Thank you! Goodbye! — ATM goodbye message
Welcome!
Please enter your account number: _____ Account-number prompt for next user
```

**Fig. I.18** | Ending an ATM transaction session.

the menu option to exit, the ATM resets itself and displays a prompt for the next user’s account number. As Fig. 1.18 illustrates, the ATM application here behaves similarly. Choosing the menu option to exit ends only the current user’s ATM session, not the entire ATM application. To actually exit the ATM application, click the close (x) button in the upper-right corner of the **Command Prompt** window. Closing the window causes the running application to terminate.

## 1.11 Web 2.0: Going Social

The web literally exploded in the mid-to-late 1990s, but the “dot com” economic bust brought hard times in the early 2000s. The resurgence that began in 2004 or so has been named **Web 2.0**. Google is widely regarded as the signature company of Web 2.0. Some other companies with “Web 2.0 characteristics” are YouTube (video sharing), FaceBook (social networking), Twitter (microblogging), Groupon (social commerce), Foursquare (mobile check-in), Salesforce (business software offered as online services), Craigslist (free classified listings), Flickr (photo sharing), Second Life (a virtual world), Skype (Internet telephony) and Wikipedia (a free online encyclopedia).

### Google

In 1996, Stanford computer science Ph.D. candidates Larry Page and Sergey Brin began collaborating on a new search engine. In 1997, they changed the name to Google—a play on the mathematical term *googol*, a quantity represented by the number “one” followed by 100 “zeros” (or  $10^{100}$ )—a staggeringly large number. Google’s ability to return extremely accurate search results quickly helped it become the most widely used search engine and one of the most popular websites in the world.

Google continues to be an innovator in search technologies. For example, Google Goggles is a fascinating mobile app (available on Android and iPhone) that allows you to perform a Google search using a photo rather than entering text. You simply take pictures of a landmarks, books (covers or barcodes), logos, art or wine bottle labels, and Google Goggles scans the photo and returns search results. You can also take a picture of text (for example, a restaurant menu or a sign) and Google Goggles will translate it for you.

### *Web Services and Mashups*

We include in this book a substantial treatment of web services (Chapter 31) and introduce the applications-development methodology of *mashups* in which you can rapidly develop powerful and intriguing applications by combining (often free) complementary web services and other forms of information feeds (Fig. 1.19). One of the first mashups was [www.housingmaps.com](http://www.housingmaps.com), which quickly combines the real estate listings provided by [www.craigslist.org](http://www.craigslist.org) with the mapping capabilities of *Google Maps* to offer maps that show the locations of apartments for rent in a given area.

Web services source	How they're used
Google Maps	Mapping services
Facebook	Social networking
Foursquare	Mobile check-in
LinkedIn	Social networking for business
YouTube	Video search
Twitter	Microblogging
Groupon	Social commerce
Netflix	Movie rentals
eBay	Internet auctions
Wikipedia	Collaborative encyclopedia
PayPal	Payments
Last.fm	Internet radio
Amazon eCommerce	Shopping for books and more
Salesforce.com	Customer Relationship Management (CRM)
Skype	Internet telephony
Microsoft Bing	Search
Flickr	Photo sharing
Zillow	Real estate pricing
Yahoo Search	Search
WeatherBug	Weather

**Fig. 1.19** | Some popular web services ([www.programmableweb.com/apis/directory/1?sort=mashups](http://www.programmableweb.com/apis/directory/1?sort=mashups)).

### *Ajax*

**Ajax** is one of the premier Web 2.0 software technologies. Ajax helps Internet-based applications perform like desktop applications—a difficult task, given that such applications

suffer transmission delays as data is shuttled back and forth between your computer and server computers on the Internet. Using Ajax, applications like Google Maps have achieved excellent performance and approach the look-and-feel of desktop applications. Although we don't discuss "raw" Ajax programming (which is quite complex) in this text, we do show in Chapter 30 how to build Ajax-enabled applications using JavaServer Faces (JSF) Ajax-enabled components.

### *Social Applications*

Over the last several years, there's been a tremendous increase in the number of social applications on the web. Even though the computer industry is mature, these sites were still able to become phenomenally successful in a relatively short period of time. Figure 1.20 discusses a few of the social applications that are making an impact.

Company	Description
Facebook	Facebook was launched from a Harvard dorm room in 2004 by classmates Mark Zuckerberg, Chris Hughes, Dustin Moskovitz and Eduardo Saverin and is already worth an estimated \$70 billion. By January 2011, Facebook was the most active site on the Internet with more than 600 million users—nearly 9% of the Earth's population—who spend 700 billion minutes on Facebook per month ( <a href="http://www.time.com/time/specials/packages/article/0,28804,2036683_2037183,00.html">www.time.com/time/specials/packages/article/0,28804,2036683_2037183,00.html</a> ). At its current growth rate (about 5% per month), Facebook will reach one billion users in 2012, out of the two billion Internet users! The activity on the site makes it extremely attractive for application developers. Each day, over 20 million applications are installed by Facebook users ( <a href="http://www.facebook.com/press/info.php?statistics">www.facebook.com/press/info.php?statistics</a> ).
Twitter	Twitter was founded in 2006 by Jack Dorsey, Evan Williams and Isaac "Biz" Stone—all from the podcast company, Odeo. Twitter has revolutionized <i>microblogging</i> . Users post tweets—messages of up to 140 characters long. Approximately 95 million tweets are posted per day ( <a href="http://twitter.com/about">twitter.com/about</a> ). You can follow the tweets of friends, celebrities, businesses, government representatives (including the U.S. President, who has 6.3 million followers), etc., or you can follow tweets by subject to track news, trends and more. At the time of this writing, Lady Gaga had the most followers (over 7.7 million). Twitter has become the point of origin for many breaking news stories worldwide.
Groupon	Groupon, a <i>social commerce</i> site, was launched by Andrew Mason in 2008. By January 2011, the company was valued around \$15 billion, making it the fastest growing company ever! It's now available in hundreds of markets worldwide. Groupon offers one daily deal in each market for restaurants, retailers, services, attractions and more. Deals are activated only after a minimum number of people sign up to buy the product or service. If you sign up for a deal and it has yet to meet the minimum, you might be inclined to tell others about the deal by email, Facebook, Twitter, etc. If the deal does not meet the minimum sales, it's cancelled. One of the most successful national Groupon deals to date was a certificate for \$50 worth of merchandise from a major apparel company for \$25. Over 440,000 vouchers were sold in one day.

**Fig. 1.20** | Social applications. (Part 1 of 2.)

Company	Description
Foursquare	Foursquare—launched in 2009 by Dennis Crowley and Naveen Selvadurai—is a mobile <i>check-in</i> application that allows you to notify your friends of your whereabouts. You can download the app to your smartphone and link it to your Facebook and Twitter accounts so your friends can follow you from multiple platforms. If you do not have a smartphone, you can check in by text message. Foursquare uses GPS to determine your exact location. Businesses use Foursquare to send offers to users in the area. Launched in March 2009, Foursquare already has over 5 million users worldwide.
Skype	Skype is a software product that allows you to make mostly free voice and video calls over the Internet using a technology called <i>Voice over IP</i> (IP stands for “Internet Protocol”). Skype was founded in 2003 by Niklas Zennström and Dane Janus Friis. Just two years later, the company was sold to eBay for \$2.6 billion.
YouTube	YouTube is a video-sharing site that was founded in 2005. Within one year, the company was purchased by Google for \$1.65 billion. YouTube now accounts for 10% of all Internet traffic ( <a href="http://www.webpronews.com/topnews/2010/04/16/facebook-and-youtube-get-the-most-business-internet-traffic">www.webpronews.com/topnews/2010/04/16/facebook-and-youtube-get-the-most-business-internet-traffic</a> ). Within one week of the release of Apple’s iPhone 3GS—the first iPhone model to offer video—mobile uploads to YouTube grew 400% ( <a href="http://www.hypebot.com/hypebot/2009/06/youtube-reports-1700-jump-in-mobile-video.html">www.hypebot.com/hypebot/2009/06/youtube-reports-1700-jump-in-mobile-video.html</a> ).

**Fig. 1.20** | Social applications. (Part 2 of 2.)

## 1.12 Software Technologies

Figure 1.21 lists a number of buzzwords that you’ll hear in the software development community. We’ve created Resource Centers on most of these topics, with more on the way.

Technology	Description
Agile software development	<b>Agile software development</b> is a set of methodologies that try to get software implemented faster and using fewer resources than previous methodologies. Check out the Agile Alliance ( <a href="http://www.agilealliance.org">www.agilealliance.org</a> ) and the Agile Manifesto ( <a href="http://www.agilemanifesto.org">www.agilemanifesto.org</a> ).
Refactoring	<b>Refactoring</b> involves reworking programs to make them clearer and easier to maintain while preserving their correctness and functionality. It’s widely employed with agile development methodologies. Many IDEs contain built-in <i>refactoring tools</i> to do major portions of the reworking automatically.
Design patterns	<b>Design patterns</b> are proven architectures for constructing flexible and maintainable object-oriented software. The field of design patterns tries to enumerate those recurring patterns, encouraging software designers to <i>reuse</i> them to develop better-quality software using less time, money and effort. We discuss Java design patterns in Appendix Q.

**Fig. 1.21** | Software technologies. (Part 1 of 2.)

Technology	Description
LAMP	MySQL is an open-source database management system. PHP is the most popular open-source server-side “scripting” language for developing web applications. <b>LAMP</b> is an acronym for the open-source technologies that many developers use to build web applications—it stands for Linux, Apache, MySQL and PHP (or Perl or Python—two other scripting languages).
Software as a Service (SaaS)	Software has generally been viewed as a product; most software still is offered this way. To run an application, you buy it from a software vendor. You then install it on your computer and run it as needed. As new versions appear, you upgrade the software, often at considerable expense. This process can be cumbersome for organizations with tens of thousands of systems that must be maintained on a diverse array of computer equipment. With <b>Software as a Service (SaaS)</b> , the software runs on servers elsewhere on the Internet. When that server is updated, all clients worldwide see the new capabilities—no local installation is needed. You access the service through a browser. Browsers are quite portable, so you can run the same applications on a wide variety of computers from anywhere in the world. Salesforce.com, Google, and Microsoft’s Office Live and Windows Live all offer SaaS.
Platform as a Service (PaaS)	<b>Platform as a Service (PaaS)</b> provides a computing platform for developing and running applications as a service over the web, rather than installing the tools on your computer. PaaS providers include Google App Engine, Amazon EC2, Bungee Labs and more.
Cloud computing	SaaS and PaaS are examples of <b>cloud computing</b> in which software, platforms and infrastructure (e.g., processing power and storage) are hosted on demand over the Internet. This provides users with flexibility, scalability and cost savings. For example, consider a company’s data storage needs which can fluctuate significantly over the course of a year. Rather than investing in large-scale storage hardware—which can be costly to purchase, maintain and secure, and would most likely not be used to capacity at all times—the company could purchase cloud-based services (such as Amazon S3, Google Storage, Microsoft Windows Azure™, Nirvanix™ and others) dynamically as needed.
Software Development Kit (SDK)	<b>Software Development Kits (SDKs)</b> include the tools and documentation developers use to program applications. For example, you’ll use the Java Development Kit (JDK) to build and run Java applications.

**Fig. 1.21** | Software technologies. (Part 2 of 2.)

Figure 1.22 describes software product release categories.

Version	Description
Alpha	<i>Alpha</i> software is the earliest release of a software product that’s still under active development. Alpha versions are often buggy, incomplete and unstable, and are released to a relatively small number of developers for testing new features, getting early feedback, etc.

**Fig. 1.22** | Software product release terminology. (Part 1 of 2.)

Version	Description
Beta	<i>Beta</i> versions are released to a larger number of developers later in the development process after most major bugs have been fixed and new features are nearly complete. Beta software is more stable, but still subject to change.
Release candidates	<i>Release candidates</i> are generally <i>feature complete</i> and (supposedly) bug free, and ready for use by the community, which provides a diverse testing environment—the software is used on different systems, with varying constraints and for a variety of purposes. Any bugs that appear are corrected and eventually the final product is released to the general public. Software companies often distribute incremental updates over the Internet.
Continuous beta	Software that's developed using this approach generally does not have version numbers (for example, Google search or Gmail). The software, which is hosted in the cloud (not installed on your computer), is constantly evolving so that users always have the latest version.

**Fig. 1.22** | Software product release terminology. (Part 2 of 2.)

## 1.13 Keeping Up-to-Date with Information Technologies

Figure 1.23 lists key technical and business publications that will help you stay up-to-date with the latest news and trends and technology. You can also find a growing list of Internet- and web-related Resource Centers at [www.deitel.com/ResourceCenters.html](http://www.deitel.com/ResourceCenters.html).

## 1.14 Wrap-Up

In this chapter we discussed computer hardware, software, programming languages and operating systems. We overviewed a typical Java program development environment and you test-drove a Java application. We introduced the basics of object technology. You learned about some of the exciting recent developments in the computer field. We also discussed some key software development terminology.

In Chapter 2, you'll create your first Java applications. You'll see how programs display messages on the screen and obtain information from the user at the keyboard for processing. You'll use Java's primitive data types and arithmetic operators in calculations and use Java's equality and relational operators to write simple decision-making statements.

### Self-Review Exercises

- 1.1** Fill in the blanks in each of the following statements:
- The company that popularized personal computing was \_\_\_\_\_.
  - The computer that made personal computing legitimate in business and industry was the \_\_\_\_\_.
  - Computers process data under the control of sets of instructions called \_\_\_\_\_.
  - The key logical units of the computer are the \_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - The three types of languages discussed in the chapter are \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - The programs that translate high-level language programs into machine language are called \_\_\_\_\_.
  - \_\_\_\_\_ is a smartphone operating system based on the Linux kernel and Java.
  - \_\_\_\_\_ software is generally feature complete and (supposedly) bug free, and ready for use by the community.
  - The Wii Remote, as well as many smartphones, use a(n) \_\_\_\_\_ which allows the device to respond to motion.
- 1.2** Fill in the blanks in each of the following sentences about the Java environment:
- The \_\_\_\_\_ command from the JDK executes a Java application.
  - The \_\_\_\_\_ command from the JDK compiles a Java program.
  - A Java program file must end with the \_\_\_\_\_ file extension.
  - When a Java program is compiled, the file produced by the compiler ends with the \_\_\_\_\_ file extension.
  - The file produced by the Java compiler contains \_\_\_\_\_ that are executed by the Java Virtual Machine.
- 1.3** Fill in the blanks in each of the following statements (based on Section 1.6):
- Objects have the property of \_\_\_\_\_—although objects may know how to communicate with one another across well-defined interfaces, they normally are not allowed to know how other objects are implemented.
  - Java programmers concentrate on creating \_\_\_\_\_, which contain fields and the set of methods that manipulate those fields and provide services to clients.
  - The process of analyzing and designing a system from an object-oriented point of view is called \_\_\_\_\_.
  - With \_\_\_\_\_, new classes of objects are derived by absorbing characteristics of existing classes, then adding unique characteristics of their own.

- e) \_\_\_\_\_ is a graphical language that allows people who design software systems to use an industry-standard notation to represent them.
- f) The size, shape, color and weight of an object are considered \_\_\_\_\_ of the object's class.

## Answers to Self-Review Exercises

**1.1** a) Apple. b) IBM Personal Computer. c) programs. d) input unit, output unit, memory unit, central processing unit, arithmetic and logic unit, secondary storage unit. e) machine languages, assembly languages, high-level languages. f) compilers. g) Android. h) Release candidate. i) accelerometer.

**1.2** a) java. b) javac. c) .java. d) .class. e) bytecodes.

**1.3** a) information hiding. b) classes. c) object-oriented analysis and design (OOAD). d) inheritance. e) The Unified Modeling Language (UML). f) attributes.

## Exercises

**1.4** Fill in the blanks in each of the following statements:

- a) The logical unit of the computer that receives information from outside the computer for use by the computer is the \_\_\_\_\_.
- b) The process of instructing the computer to solve a problem is called \_\_\_\_\_.
- c) \_\_\_\_\_ is a type of computer language that uses English-like abbreviations for machine-language instructions.
- d) \_\_\_\_\_ is a logical unit of the computer that sends information which has already been processed by the computer to various devices so that it may be used outside the computer.
- e) \_\_\_\_\_ and \_\_\_\_\_ are logical units of the computer that retain information.
- f) \_\_\_\_\_ is a logical unit of the computer that performs calculations.
- g) \_\_\_\_\_ is a logical unit of the computer that makes logical decisions.
- h) \_\_\_\_\_ languages are most convenient to the programmer for writing programs quickly and easily.
- i) The only language a computer can directly understand is that computer's \_\_\_\_\_.
- j) \_\_\_\_\_ is a logical unit of the computer that coordinates the activities of all the other logical units.

**1.5** Fill in the blanks in each of the following statements:

- a) \_\_\_\_\_ is now used to develop large-scale enterprise applications, to enhance the functionality of web servers, to provide applications for consumer devices and for many other purposes.
- b) \_\_\_\_\_ initially became widely known as the development language of the Unix operating system.
- c) The Web 2.0 company \_\_\_\_\_ is the fastest growing company ever.
- d) The \_\_\_\_\_ programming language was developed by Bjarne Stroustrup in the early 1980s at Bell Laboratories.

**1.6** Fill in the blanks in each of the following statements:

- a) Java programs normally go through five phases—\_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
- b) A(n) \_\_\_\_\_ provides many tools that support the software development process, such as editors for writing and editing programs, debuggers for locating logic errors in programs, and many other features.

- c) The command `java` invokes the \_\_\_\_\_, which executes Java programs.
- d) A(n) \_\_\_\_\_ is a software application that simulates a computer, but hides the underlying operating system and hardware from the programs that interact with it.
- e) The \_\_\_\_\_ takes the `.class` files containing the program's bytecodes and transfers them to primary memory.
- f) The \_\_\_\_\_ examines bytecodes to ensure that they're valid.

**1.7** Explain the two compilation phases of Java programs.

**1.8** You're probably wearing on your wrist one of the world's most common types of objects—a watch. Discuss how each of the following terms and concepts applies to the notion of a watch: object, attributes, behaviors, class, inheritance (consider, for example, an alarm clock), abstraction, modeling, messages, encapsulation, interface and information hiding.

## Making a Difference

Throughout the book we've included Making a Difference exercises in which you'll be asked to work on problems that really matter to individuals, communities, countries and the world. For more information about worldwide organizations working to make a difference, and for related programming project ideas, visit our Making a Difference Resource Center at [www.deitel.com/makingadifference](http://www.deitel.com/makingadifference).

**1.9** (*Test Drive: Carbon Footprint Calculator*) Some scientists believe that carbon emissions, especially from the burning of fossil fuels, contribute significantly to global warming and that this can be combatted if individuals take steps to limit their use of carbon-based fuels. Organizations and individuals are increasingly concerned about their “carbon footprints.” Websites such as TerraPass

[www.terrapass.com/carbon-footprint-calculator/](http://www.terrapass.com/carbon-footprint-calculator/)

and Carbon Footprint

[www.carbonfootprint.com/calculator.aspx](http://www.carbonfootprint.com/calculator.aspx)

provide carbon footprint calculators. Test-drive these calculators to determine your carbon footprint. Exercises in later chapters will ask you to program your own carbon footprint calculator. To prepare for this, research the formulas for calculating carbon footprints.

**1.10** (*Test Drive: Body Mass Index Calculator*) By recent estimates, two-thirds of the people in the United States are overweight and about half of those are obese. This causes significant increases in illnesses such as diabetes and heart disease. To determine whether a person is overweight or obese, you can use a measure called the body mass index (BMI). The United States Department of Health and Human Services provides a BMI calculator at [www.nhlbhsupport.com/bmi/](http://www.nhlbhsupport.com/bmi/). Use it to calculate your own BMI. An exercise in Chapter 2 will ask you to program your own BMI calculator. To prepare for this, research the formulas for calculating BMI.

**1.11** (*Attributes of Hybrid Vehicles*) In this chapter you learned the basics of classes. Now you'll begin “fleshing out” aspects of a class called “Hybrid Vehicle.” Hybrid vehicles are becoming increasingly popular, because they often get much better mileage than purely gasoline-powered vehicles. Browse the web and study the features of four or five of today's popular hybrid cars, then list as many of their hybrid-related attributes as you can. For example, common attributes include city-miles-per-gallon and highway-miles-per-gallon. Also list the attributes of the batteries (type, weight, etc.).

**1.12** (*Gender Neutrality*) Many people want to eliminate sexism in all forms of communication. You've been asked to create a program that can process a paragraph of text and replace gender-specific words with gender-neutral ones. Assuming that you've been given a list of gender-specific words and their gender-neutral replacements (e.g., replace “wife” by “spouse,” “man” by “person,” “daughter” by “child” and so on), explain the procedure you'd use to read through a paragraph of text and manually perform these replacements. How might your procedure generate a strange term

like “woperchild,” which is actually listed in the Urban Dictionary ([www.urbandictionary.com](http://www.urbandictionary.com))? In Chapter 4, you’ll learn that a more formal term for “procedure” is “algorithm,” and that an algorithm specifies the steps to be performed and the order in which to perform them.

**1.13 (Privacy)** Some online email services save all email correspondence for some period of time. Suppose a disgruntled employee of one of these online email services were to post all of the email correspondences for millions of people, including yours, on the Internet. Discuss the issues.

**1.14 (Programmer Responsibility and Liability)** As a programmer in industry, you may develop software that could affect people’s health or even their lives. Suppose a software bug in one of your programs were to cause a cancer patient to receive an excessive dose during radiation therapy and that the person is either severely injured or dies. Discuss the issues.

**1.15 (2010 “Flash Crash”)** An example of the consequences of our excessive dependency on computers was the so-called “flash crash” which occurred on May 6, 2010, when the U.S. stock market fell precipitously in a matter of minutes, wiping out trillions of dollars of investments, and then recovered within minutes. Use the Internet to investigate the causes of this crash and discuss the issues it raises.

## Making a Difference Resources

The *Microsoft Image Cup* is a global competition in which students use technology to try to solve some of the world’s most difficult problems, such as environmental sustainability, ending hunger, emergency response, literacy, combating HIV/AIDS and more. Visit [www.imaginecup.com/about](http://www.imaginecup.com/about) for more information about the competition and to learn about the projects developed by previous winners. You can also find several project ideas submitted by worldwide charitable organizations at [www.imaginecup.com/students/imagine-cup-solve-this](http://www.imaginecup.com/students/imagine-cup-solve-this). For additional ideas for programming projects that can make a difference, search the web for “making a difference” and visit the following websites:

[www.un.org/millenniumgoals](http://www.un.org/millenniumgoals)

The United Nations Millennium Project seeks solutions to major worldwide issues such as environmental sustainability, gender equality, child and maternal health, universal education and more.

[www.ibm.com/smarterplanet/](http://www.ibm.com/smarterplanet/)

The IBM® Smarter Planet website discusses how IBM is using technology to solve issues related to business, cloud computing, education, sustainability and more.

[www.gatesfoundation.org/Pages/home.aspx](http://www.gatesfoundation.org/Pages/home.aspx)

The Bill and Melinda Gates Foundation provides grants to organizations that work to alleviate hunger, poverty and disease in developing countries. In the United States, the foundation focusses on improving public education, particularly for people with few resources.

[www.nethope.org/](http://www.nethope.org/)

NetHope is a collaboration of humanitarian organizations worldwide working to solve technology problems such as connectivity, emergency response and more.

[www.rainforestfoundation.org/home](http://www.rainforestfoundation.org/home)

The Rainforest Foundation works to preserve rainforests and to protect the rights of the indigenous people who call the rainforests home. The site includes a list of things you can do to help.

[www.undp.org/](http://www.undp.org/)

The United Nations Development Programme (UNDP) seeks solutions to global challenges such as crisis prevention and recovery, energy and the environment, democratic governance and more.

[www.unido.org](http://www.unido.org)

The United Nations Industrial Development Organization (UNIDO) seeks to reduce poverty, give developing countries the opportunity to participate in global trade, and promote energy efficiency and sustainability.

[www.usaid.gov/](http://www.usaid.gov/)

USAID promotes global democracy, health, economic growth, conflict prevention, humanitarian aid and more.

[www.toyota.com/ideas-for-good/](http://www.toyota.com/ideas-for-good/)

Toyota's Ideas for Good website describes several Toyota technologies that are making a difference—including their Advanced Parking Guidance System, Hybrid Synergy Drive®, Solar Powered Ventilation System, T.H.U.M.S. (Total Human Model for Safety) and Touch Tracer Display. You can participate in the Ideas for Good challenge by submitting a short essay or video describing how these technologies can be used for other good purposes.

# Introduction to Java Applications

*What's in a name?  
That which we call a rose  
By any other name would  
smell as sweet.*

—William Shakespeare

*When faced with a decision,  
I always ask, "What would be  
the most fun?"*

—Peggy Walker

*The chief merit of language  
is clearness.*

—Galen

*One person can make a  
difference and every person  
should try.*

—John F. Kennedy

## Objectives

In this chapter you'll learn:

- To write simple Java applications.
- To use input and output statements.
- Java's primitive types.
- Basic memory concepts.
- To use arithmetic operators.
- The precedence of arithmetic operators.
- To write decision-making statements.
- To use relational and equality operators.

- |  |   |

| <b>2.3</b> Modifying Your First Java Program                   | <b>2.8</b> Decision Making: Equality and Relational Operators |
| <b>2.4</b> Displaying Text with <code>printf</code>            | <b>2.9</b> Wrap-Up  |
| <b>2.5</b> Another Application: Adding Integers                |   |

Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference

## 2.1 Introduction

This chapter introduces Java application programming. We begin with examples of programs that display messages on the screen. We then present a program that obtains two numbers from a user, calculates their sum and displays the result. You'll learn how to instruct the computer to perform arithmetic calculations and save their results for later use. The last example demonstrates how to make decisions. The application compares numbers, then displays messages that show the comparison results.

This chapter uses tools from the JDK to compile and run programs. We've also posted Dive Into® videos at [www.deitel.com/books/jhttp9/](http://www.deitel.com/books/jhttp9/) to help you get started with the popular Eclipse and NetBeans integrated development environments.

## 2.2 Your First Program in Java: Printing a Line of Text

A Java **application** is a computer program that executes when you use the **java command** to launch the Java Virtual Machine (JVM). Later in this section we'll discuss how to compile and run a Java application. First we consider a simple application that displays a line of text. Figure 2.1 shows the program followed by a box that displays its output. The program includes line numbers. We've added these for instructional purposes—they're *not* part of a Java program. This example illustrates several important Java features. We'll see that line 9 does the real work—displaying the phrase Welcome to Java Programming! on the screen.

```

1 // Fig. 2.1: Welcome1.java
2 // Text-printing program.
3
4 public class Welcome1
5 {
6     // main method begins execution of Java application
7     public static void main( String[] args )
8     {
9         System.out.println( "Welcome to Java Programming!" );
10    } // end method main
11 } // end class Welcome1

```

```
Welcome to Java Programming!
```

**Fig. 2.1** | Text-printing program.

### Commenting Your Programs

We insert **comments** to **document programs** and improve their readability. The Java compiler ignores comments, so they do *not* cause the computer to perform any action when the program is run.

By convention, we begin every program with a comment indicating the figure number and file name. The comment in line 1

```
// Fig. 2.1: Welcome1.java
```

begins with `//`, indicating that it is an **end-of-line comment**—it terminates at the end of the line on which the `//` appears. An end-of-line comment need not begin a line; it also can begin in the middle of a line and continue until the end (as in lines 10 and 11). Line 2

```
// Text-printing program.
```

is a comment that describes the purpose of the program.

Java also has **traditional comments**, which can be spread over several lines as in

```
/* This is a traditional comment. It
   can be split over multiple lines */
```

These begin and end with delimiters, `/*` and `*/`. The compiler ignores all text between the delimiters. Java incorporated traditional comments and end-of-line comments from the C and C++ programming languages, respectively. In this book, we use only `//` comments.

Java provides comments of a third type, **Javadoc comments**. These are delimited by `/**` and `*/`. The compiler ignores all text between the delimiters. Javadoc comments enable you to embed program documentation directly in your programs. Such comments are the preferred Java documenting format in industry. The **javadoc utility program** (part of the Java SE Development Kit) reads Javadoc comments and uses them to prepare your program's documentation in HTML format. We demonstrate Javadoc comments and the javadoc utility in Appendix M, Creating Documentation with javadoc.

#### Common Programming Error 2.1

*Forgetting one of the delimiters of a traditional or Javadoc comment is a syntax error. A **syntax error** occurs when the compiler encounters code that violates Java's language rules (i.e., its syntax). These rules are similar to a natural language's grammar rules specifying sentence structure. Syntax errors are also called **compiler errors**, **compile-time errors** or **compilation errors**, because the compiler detects them during the compilation phase. The compiler responds by issuing an error message and preventing your program from compiling.*

#### Good Programming Practice 2.1

*Some organizations require that every program begin with a comment that states the purpose of the program and the author, date and time when the program was last modified.*

### Using Blank Lines

Line 3 is a blank line. Blank lines, space characters and tabs make programs easier to read. Together, they're known as **white space** (or whitespace). The compiler ignores white space.

#### Good Programming Practice 2.2

*Use blank lines and spaces to enhance program readability.*

## Declaring a Class

Line 4

```
public class Welcome1
```

begins a **class declaration** for class `Welcome1`. Every Java program consists of at least one class that you (the programmer) define. The **class keyword** introduces a class declaration and is immediately followed by the **class name** (`Welcome1`). **Keywords** (sometimes called **reserved words**) are reserved for use by Java and are always spelled with all lowercase letters. The complete list of keywords is shown in Appendix C.

### Class Names and Identifiers

By convention, class names begin with a capital letter and capitalize the first letter of each word they include (e.g., `SampleClassName`). A class name is an **identifier**—a series of characters consisting of letters, digits, underscores (`_`) and dollar signs (`$`) that does not begin with a digit and does not contain spaces. Some valid identifiers are `Welcome1`, `$value`, `_value`, `m_inputField1` and `button7`. The name `7button` is not a valid identifier because it begins with a digit, and the name `input field` is not a valid identifier because it contains a space. Normally, an identifier that does not begin with a capital letter is not a class name. Java is **case sensitive**—uppercase and lowercase letters are distinct—so `value` and `Value` are different (but both valid) identifiers.

In Chapters 2–7, every class we define begins with the **public** keyword. For now, we simply require this keyword. For our application, the file name is `Welcome1.java`. You'll learn more about **public** and **non-public** classes in Chapter 8.

### Common Programming Error 2.2

*A **public** class must be placed in a file that has the same name as the class (in terms of both spelling and capitalization) plus the `.java` extension; otherwise, a compilation error occurs. For example, `public class Welcome` must be placed in a file named `Welcome.java`.*

A **left brace** (as in line 5), `{`, begins the **body** of every class declaration. A corresponding **right brace** (at line 11), `}`, must end each class declaration. Lines 6–10 are indented.

### Error-Prevention Tip 2.1

*When you type an opening left brace, `{`, immediately type the closing right brace, `}`, then reposition the cursor between the braces and indent to begin typing the body. This practice helps prevent errors due to missing braces. Many IDEs insert the braces for you.*

### Common Programming Error 2.3

*It's a syntax error if braces do not occur in matching pairs.*

### Good Programming Practice 2.3

*Indent the entire body of each class declaration one “level” between the left brace and the right brace that delimit the body of the class. We recommend using three spaces to form a level of indent. This format emphasizes the class declaration's structure and makes it easier to read.*

### Good Programming Practice 2.4

Many IDEs insert indentation for you in all the right places. The Tab key may also be used to indent code, but tab stops vary among text editors. Most IDEs allow you to configure tabs such that a specified number of spaces is inserted each time you press the Tab key.

### Declaring a Method

Line 6

```
// main method begins execution of Java application
```

is an end-of-line comment indicating the purpose of lines 7–10 of the program. Line 7

```
public static void main( String[] args )
```

is the starting point of every Java application. The **parentheses** after the identifier `main` indicate that it's a program building block called a **method**. Java class declarations normally contain one or more methods. For a Java application, one of the methods *must* be called `main` and must be defined as shown in line 7; otherwise, the Java Virtual Machine (JVM) will not execute the application. Methods perform tasks and can return information when they complete their tasks. Keyword **void** indicates that this method will *not* return any information. Later, we'll see how a method can return information. For now, simply mimic `main`'s first line in your Java applications. In line 7, the `String[] args` in parentheses is a required part of the method `main`'s declaration—we discuss this in Chapter 7.

The left brace in line 8 begins the **body of the method declaration**. A corresponding right brace must end it (line 10). Line 9 in the method body is indented between the braces.

### Good Programming Practice 2.5

Indent the entire body of each method declaration one “level” between the braces that define the body of the method. This makes the structure of the method stand out and makes the method declaration easier to read.

### Performing Output with `System.out.println`

Line 9

```
System.out.println( "Welcome to Java Programming!" );
```

instructs the computer to perform an action—namely, to print the **string** of characters contained between the double quotation marks (but not the quotation marks themselves). A string is sometimes called a **character string** or a **string literal**. White-space characters in strings are *not* ignored by the compiler. Strings cannot span multiple lines of code, but as you'll see later, this does not restrict you from using long strings in your code.

The **System.out** object is known as the **standard output object**. It allows a Java application to display information in the **command window** from which it executes. In recent versions of Microsoft Windows, the command window is the **Command Prompt**. In UNIX/Linux/Mac OS X, the command window is called a **terminal window** or a **shell**. Many programmers call it simply the **command line**.

Method **System.out.println** displays (or prints) a line of text in the command window. The string in the parentheses in line 9 is the **argument** to the method. When `System.out.println` completes its task, it positions the output cursor (the location where the next character will be displayed) at the beginning of the next line in the command

window. This is similar to what happens when you press the *Enter* key while typing in a text editor—the cursor appears at the beginning of the next line in the document.

The entire line 9, including `System.out.println`, the argument "Welcome to Java Programming!" in the parentheses and the **semicolon** (`;`), is called a **statement**. A method typically contains one or more statements that perform its task. Most statements end with a semicolon. When the statement in line 9 executes, it displays `Welcome to Java Programming!` in the command window.

### Error-Prevention Tip 2.2

*When learning how to program, sometimes it's helpful to "break" a working program so you can familiarize yourself with the compiler's syntax-error messages. These messages do not always state the exact problem in the code. When you encounter an error message, it will give you an idea of what caused the error. [Try removing a semicolon or brace from the program of Fig. 2.1, then recompile the program to see the error messages generated by the omission.]*

### Error-Prevention Tip 2.3

*When the compiler reports a syntax error, it may not be on the line that the error message indicates. First, check the line for which the error was reported. If you don't find an error on that line,, check several preceding lines.*

### *Using End-of-Line Comments on Right Braces for Readability*

We include an end-of-line comment after a closing brace that ends a method declaration and after a closing brace that ends a class declaration. For example, line 10

```
} // end method main
```

indicates the closing brace of method `main`, and line 11

```
} // end class Welcome1
```

indicates the closing brace of class `Welcome1`. Each comment indicates the method or class that the right brace terminates.

### *Compiling and Executing Your First Java Application*

We're now ready to compile and execute our program. We assume you're using the Java Development Kit's command-line tools, not an IDE. Our Java Resource Centers at [www.deitel.com/ResourceCenters.html](http://www.deitel.com/ResourceCenters.html) provide links to tutorials that help you get started with several popular Java development tools, including NetBeans™, Eclipse™ and others. We've also posted NetBeans and Eclipse videos at [www.deitel.com/books/jhttp9/](http://www.deitel.com/books/jhttp9/) to help you get started using these popular IDEs.

To prepare to compile the program, open a command window and change to the directory where the program is stored. Many operating systems use the command `cd` to change directories. On Windows, for example,

```
cd c:\examples\ch02\fig02_01
```

changes to the `fig02_01` directory. On UNIX/Linux/Mac OS X, the command

```
cd ~/examples/ch02/fig02_01
```

changes to the `fig02_01` directory.

To compile the program, type

```
javac Welcome1.java
```

If the program contains no syntax errors, this command creates a new file called `Welcome1.class` (known as the **class file** for `Welcome1`) containing the platform-independent Java bytecodes that represent our application. When we use the `java` command to execute the application on a given platform, the JVM will translate these bytecodes into instructions that are understood by the underlying operating system and hardware.

#### Error-Prevention Tip 2.4

When attempting to compile a program, if you receive a message such as “bad command or filename,” “javac: command not found” or “'javac' is not recognized as an internal or external command, operable program or batch file,” then your Java software installation was not completed properly. If you’re using the JDK, this indicates that the system’s `PATH` environment variable was not set properly. Please carefully review the installation instructions in the *Before You Begin* section of this book. On some systems, after correcting the `PATH`, you may need to reboot your computer or open a new command window for these settings to take effect.

#### Error-Prevention Tip 2.5

Each syntax-error message contains the file name and line number where the error occurred. For example, `Welcome1.java:6` indicates that an error occurred at line 6 in `Welcome1.java`. The rest of the message provides information about the syntax error.

#### Error-Prevention Tip 2.6

The compiler error message “class `Welcome1` is public, should be declared in a file named `Welcome1.java`” indicates that the file name does not match the name of the public class in the file or that you typed the class name incorrectly when compiling the class.

Figure 2.2 shows the program of Fig. 2.1 executing in a Microsoft® Windows® 7 **Command Prompt** window. To execute the program, type `java Welcome1`. This command launches the JVM, which loads the `.class` file for class `Welcome1`. The command omits the `.class` file-name extension; otherwise, the JVM will not execute the program. The JVM calls method `main`. Next, the statement at line 9 of `main` displays “Welcome to Java Programming!” [Note: Many environments show command prompts with black backgrounds and white text. We adjusted these settings in our environment to make our screen captures more readable.]

```

Select Command Prompt
C:\examples\ch02\fig02_01>javac Welcome1.java
C:\examples\ch02\fig02_01>java Welcome1
Welcome to Java Programming!
C:\examples\ch02\fig02_01>

```

You type this command to execute the application

The program outputs to the screen  
Welcome to Java Programming!

**Fig. 2.2** | Executing `Welcome1` from the **Command Prompt**.

### Error-Prevention Tip 2.7

When attempting to run a Java program, if you receive a message such as “Exception in thread “main” java.lang.NoClassDefFoundError: Welcome1,” your CLASSPATH environment variable has not been set properly. Please carefully review the installation instructions in the *Before You Begin* section of this book. On some systems, you may need to reboot your computer or open a new command window after configuring the CLASSPATH.

## 2.3 Modifying Your First Java Program

In this section, we modify the example in Fig. 2.1 to print text on one line by using multiple statements and to print text on several lines by using a single statement.

### *Displaying a Single Line of Text with Multiple Statements*

Welcome to Java Programming! can be displayed several ways. Class Welcome2, shown in Fig. 2.3, uses two statements (lines 9–10) to produce the output shown in Fig. 2.1. [Note: From this point forward, we highlight the new and key features in each code listing, as we’ve done for lines 9–10.]

```

1 // Fig. 2.3: Welcome2.java
2 // Printing a line of text with multiple statements.
3
4 public class Welcome2
5 {
6     // main method begins execution of Java application
7     public static void main( String[] args )
8     {
9         System.out.print( "Welcome to " );
10        System.out.println( "Java Programming!" );
11    } // end method main
12 } // end class Welcome2

```

```
Welcome to Java Programming!
```

**Fig. 2.3** | Printing a line of text with multiple statements.

The program is similar to Fig. 2.1, so we discuss only the changes here. Line 2

```
// Printing a line of text with multiple statements.
```

is an end-of-line comment stating the purpose of the program. Line 4 begins the Welcome2 class declaration. Lines 9–10 of method main

```
System.out.print( "Welcome to " );
System.out.println( "Java Programming!" );
```

display one line of text. The first statement uses System.out’s method print to display a string. Each print or println statement resumes displaying characters from where the last print or println statement stopped displaying characters. Unlike println, after displaying its argument, print does *not* position the output cursor at the beginning of the next line in the command window—the next character the program displays will appear *immediately after* the last character that print displays. Thus, line 10 positions the first character

in its argument (the letter “J”) immediately after the last character that line 9 displays (the *space character* before the string’s closing double-quote character).

### Displaying Multiple Lines of Text with a Single Statement

A single statement can display multiple lines by using **newline characters**, which indicate to `System.out`’s `print` and `println` methods when to position the output cursor at the beginning of the next line in the command window. Like blank lines, space characters and tab characters, newline characters are white-space characters. The program in Fig. 2.4 outputs four lines of text, using newline characters to determine when to begin each new line. Most of the program is identical to those in Fig. 2.1 and Fig. 2.3.

```

1 // Fig. 2.4: Welcome3.java
2 // Printing multiple lines of text with a single statement.
3
4 public class Welcome3
5 {
6     // main method begins execution of Java application
7     public static void main( String[] args )
8     {
9         System.out.println( "Welcome\n\tto\n\tJava\n\tProgramming!" );
10    } // end method main
11 } // end class Welcome3

```

```

Welcome
to
Java
Programming!

```

**Fig. 2.4** | Printing multiple lines of text with a single statement.

Line 2

```
// Printing multiple lines of text with a single statement.
```

is a comment stating the program’s purpose. Line 4 begins the `Welcome3` class declaration.

Line 9

```
System.out.println( "Welcome\n\tto\n\tJava\n\tProgramming!" );
```

displays four separate lines of text in the command window. Normally, the characters in a string are displayed *exactly* as they appear in the double quotes. Note, however, that the paired characters `\` and `n` (repeated three times in the statement) do not appear on the screen. The **backslash** (`\`) is an **escape character**, which has special meaning to `System.out`’s `print` and `println` methods. When a backslash appears in a string, Java combines it with the next character to form an **escape sequence**. The escape sequence `\n` represents the newline character. When a newline character appears in a string being output with `System.out`, the newline character causes the screen’s output cursor to move to the beginning of the next line in the command window.

Figure 2.5 lists several common escape sequences and describes how they affect the display of characters in the command window. For the complete list of escape sequences, visit [java.sun.com/docs/books/jls/third\\_edition/html/lexical.html#3.10.6](http://java.sun.com/docs/books/jls/third_edition/html/lexical.html#3.10.6).

Escape sequence	Description
<code>\n</code>	Newline. Position the screen cursor at the beginning of the next line.
<code>\t</code>	Horizontal tab. Move the screen cursor to the next tab stop.
<code>\r</code>	Carriage return. Position the screen cursor at the beginning of the current line—do <i>not</i> advance to the next line. Any characters output after the carriage return overwrite the characters previously output on that line.
<code>\\</code>	Backslash. Used to print a backslash character.
<code>\"</code>	Double quote. Used to print a double-quote character. For example, <code>System.out.println( "\"in quotes\"" );</code> displays "in quotes".

**Fig. 2.5** | Some common escape sequences.

## 2.4 Displaying Text with `printf`

The `System.out.printf` method (f means “formatted”) displays formatted data. Figure 2.6 uses this method to output the strings “Welcome to” and “Java Programming!”. Lines 9–10

```
System.out.printf( "%s\n%s\n",
    "Welcome to", "Java Programming!" );
```

call method `System.out.printf` to display the program’s output. The method call specifies three arguments. When a method requires multiple arguments, they’re placed in a **comma-separated list**.

### Good Programming Practice 2.6

*Place a space after each comma (,) in an argument list to make programs more readable.*

```
1 // Fig. 2.6: Welcome4.java
2 // Displaying multiple lines with method System.out.printf.
3
4 public class Welcome4
5 {
6     // main method begins execution of Java application
7     public static void main( String[] args )
8     {
9         System.out.printf( "%s\n%s\n",
10            "Welcome to", "Java Programming!" );
11     } // end method main
12 } // end class Welcome4
```

```
Welcome to
Java Programming!
```

**Fig. 2.6** | Displaying multiple lines with method `System.out.printf`.

Lines 9–10 represent only *one* statement. Java allows large statements to be split over many lines. We indent line 10 to indicate that it's a *continuation* of line 9.

### Common Programming Error 2.4

*Splitting a statement in the middle of an identifier or a string is a syntax error.*

Method `printf`'s first argument is a **format string** that may consist of **fixed text** and **format specifiers**. Fixed text is output by `printf` just as it would be by `print` or `println`. Each format specifier is a placeholder for a value and specifies the type of data to output. Format specifiers also may include optional formatting information.

Format specifiers begin with a percent sign (%) followed by a character that represents the data type. For example, the format specifier **%s** is a placeholder for a string. The format string in line 9 specifies that `printf` should output two strings, each followed by a newline character. At the first format specifier's position, `printf` substitutes the value of the first argument after the format string. At each subsequent format specifier's position, `printf` substitutes the value of the next argument. So this example substitutes "Welcome to" for the first %s and "Java Programming!" for the second %s. The output shows that two lines of text are displayed.

We introduce various formatting features as they're needed in our examples. Appendix G presents the details of formatting output with `printf`.

## 2.5 Another Application: Adding Integers

Our next application reads (or inputs) two **integers** (whole numbers, such as -22, 7, 0 and 1024) typed by a user at the keyboard, computes their sum and displays it. This program must keep track of the numbers supplied by the user for the calculation later in the program. Programs remember numbers and other data in the computer's memory and access that data through program elements called **variables**. The program of Fig. 2.7 demonstrates these concepts. In the sample output, we use bold text to identify the user's input (i.e., **45** and **72**).

```

1 // Fig. 2.7: Addition.java
2 // Addition program that displays the sum of two numbers.
3 import java.util.Scanner; // program uses class Scanner
4
5 public class Addition
6 {
7     // main method begins execution of Java application
8     public static void main( String[] args )
9     {
10        // create a Scanner to obtain input from the command window
11        Scanner input = new Scanner( System.in );
12
13        int number1; // first number to add
14        int number2; // second number to add
15        int sum; // sum of number1 and number2
16

```

**Fig. 2.7** | Addition program that displays the sum of two numbers. (Part 1 of 2.)

```

17     System.out.print( "Enter first integer: " ); // prompt
18     number1 = input.nextInt(); // read first number from user
19
20     System.out.print( "Enter second integer: " ); // prompt
21     number2 = input.nextInt(); // read second number from user
22
23     sum = number1 + number2; // add numbers, then store total in sum
24
25     System.out.printf( "Sum is %d\n", sum ); // display sum
26     } // end method main
27 } // end class Addition

```

```

Enter first integer: 45
Enter second integer: 72
Sum is 117

```

**Fig. 2.7** | Addition program that displays the sum of two numbers. (Part 2 of 2.)

### Import Declarations

Lines 1–2

```

// Fig. 2.7: Addition.java
// Addition program that displays the sum of two numbers.

```

state the figure number, file name and purpose of the program.

A great strength of Java is its rich set of predefined classes that you can *reuse* rather than “reinventing the wheel.” These classes are grouped into **packages**—named groups of related classes—and are collectively referred to as the **Java class library**, or the **Java Application Programming Interface (Java API)**. Line 3

```
import java.util.Scanner; // program uses class Scanner

```

is an **import declaration** that helps the compiler locate a class that’s used in this program. It indicates that this example uses Java’s predefined Scanner class (discussed shortly) from package **java.util**.

### Common Programming Error 2.5

*All import declarations must appear before the first class declaration in the file. Placing an import declaration inside or after a class declaration is a syntax error.*

### Error-Prevention Tip 2.8

*Forgetting to include an import declaration for a class used in your program typically results in a compilation error containing a message such as “cannot find symbol.” When this occurs, check that you provided the proper import declarations and that the names in them are correct, including proper capitalization.*

### Declaring Class Addition

Line 5

```
public class Addition

```

begins the declaration of class `Addition`. The file name for this `public` class must be `Addition.java`. Remember that the body of each class declaration starts with an opening left brace (line 6) and ends with a closing right brace (line 27).

The application begins execution with the `main` method (lines 8–26). The left brace (line 9) marks the beginning of method `main`'s body, and the corresponding right brace (line 26) marks its end. Method `main` is indented one level in the body of class `Addition`, and the code in the body of `main` is indented another level for readability.

### *Declaring and Creating a Scanner to Obtain User Input from the Keyboard*

A **variable** is a location in the computer's memory where a value can be stored for use later in a program. All Java variables *must* be declared with a **name** and a **type** *before* they can be used. A variable's name enables the program to access the value of the variable in memory. A variable's name can be any valid identifier. A variable's type specifies what kind of information is stored at that location in memory. Like other statements, declaration statements end with a semicolon (;).

Line 11

```
Scanner input = new Scanner( System.in );
```

is a **variable declaration statement** that specifies the name (`input`) and type (`Scanner`) of a variable that's used in this program. A **Scanner** enables a program to read data (e.g., numbers and strings) for use in a program. The data can come from many sources, such as the user at the keyboard or a file on disk. Before using a `Scanner`, you must create it and specify the source of the data.

The `=` in line 11 indicates that `Scanner` variable `input` should be **initialized** (i.e., prepared for use in the program) in its declaration with the result of the expression to the right of the equals sign—`new Scanner(System.in)`. This expression uses the **new** keyword to create a `Scanner` object that reads characters typed by the user at the keyboard. The **standard input object, `System.in`**, enables applications to read bytes of information typed by the user. The `Scanner` translates these bytes into types (like `ints`) that can be used in a program.

### *Declaring Variables to Store Integers*

The variable declaration statements in lines 13–15

```
int number1; // first number to add
int number2; // second number to add
int sum; // sum of number1 and number2
```

declare that variables `number1`, `number2` and `sum` hold data of type **int**—they can hold integer values (whole numbers such as 72, -1127 and 0). These variables are not yet initialized. The range of values for an `int` is -2,147,483,648 to +2,147,483,647. [*Note: Actual `int` values may not contain commas.*]

Other types of data include **float** and **double**, for holding real numbers, and **char**, for holding character data. Real numbers contain decimal points, such as 3.4, 0.0 and -11.19. Variables of type `char` represent individual characters, such as an uppercase letter (e.g., `A`), a digit (e.g., `7`), a special character (e.g., `*` or `%`) or an escape sequence (e.g., the newline character, `\n`). The types `int`, `float`, `double` and `char` are called **primitive types**. Primitive-type names are keywords and must appear in all lowercase letters. Appendix D summarizes the characteristics of the eight primitive types (`boolean`, `byte`, `char`, `short`, `int`, `long`, `float` and `double`).

Several variables of the same type may be declared in a single declaration with the variable names separated by commas (i.e., a comma-separated list of variable names). For example, lines 13–15 can also be written as:

```
int number1, // first number to add
    number2, // second number to add
    sum; // sum of number1 and number2
```

### Good Programming Practice 2.7

*Declare each variable on a separate line. This format allows a descriptive comment to be inserted next to each declaration.*

### Good Programming Practice 2.8

*Choosing meaningful variable names helps a program to be self-documenting (i.e., one can understand the program simply by reading it rather than by reading manuals or viewing an excessive number of comments).*

### Good Programming Practice 2.9

*By convention, variable-name identifiers begin with a lowercase letter, and every word in the name after the first word begins with a capital letter. For example, variable-name identifier `firstNumber` starts its second word, `Number`, with a capital `N`.*

## Prompting the User for Input

Line 17

```
System.out.print( "Enter first integer: " ); // prompt
```

uses `System.out.print` to display the message "Enter first integer: ". This message is called a **prompt** because it directs the user to take a specific action. We use method `print` here rather than `println` so that the user's input appears on the same line as the prompt. Recall from Section 2.2 that identifiers starting with capital letters typically represent class names. So, `System` is a class. Class `System` is part of package **java.lang**. Notice that class `System` is not imported with an `import` declaration at the beginning of the program.

### Software Engineering Observation 2.1

*By default, package `java.lang` is imported in every Java program; thus, classes in `java.lang` are the only ones in the Java API that do not require an `import` declaration.*

## Obtaining an `int` as Input from the User

Line 18

```
number1 = input.nextInt(); // read first number from user
```

uses `Scanner` object `input`'s `nextInt` method to obtain an integer from the user at the keyboard. At this point the program waits for the user to type the number and press the *Enter* key to submit the number to the program.

Our program assumes that the user enters a valid integer value. If not, a runtime logic error will occur and the program will terminate. Chapter 11, Exception Handling: A Deeper Look, discusses how to make your programs more robust by enabling them to handle such errors. This is also known as making your program *fault tolerant*.

In line 18, we place the result of the call to method `nextInt` (an `int` value) in variable `number1` by using the **assignment operator**, `=`. The statement is read as “`number1` gets the value of `input.nextInt()`.” Operator `=` is called a **binary operator**, because it has two **operands**—`number1` and the result of the method call `input.nextInt()`. This statement is called an assignment statement, because it assigns a value to a variable. Everything to the *right* of the assignment operator, `=`, is always evaluated *before* the assignment is performed.

### Good Programming Practice 2.10

*Placing spaces on either side of a binary operator makes the program more readable.*

### Prompting for and Inputting a Second `int`

Line 20

```
System.out.print( "Enter second integer: " ); // prompt
```

prompts the user to input the second integer. Line 21

```
number2 = input.nextInt(); // read second number from user
```

reads the second integer and assigns it to variable `number2`.

### Using Variables in a Calculation

Line 23

```
sum = number1 + number2; // add numbers then store total in sum
```

is an assignment statement that calculates the sum of the variables `number1` and `number2` then assigns the result to variable `sum` by using the assignment operator, `=`. The statement is read as “`sum` gets the value of `number1 + number2`.” In general, calculations are performed in assignment statements. When the program encounters the addition operation, it performs the calculation using the values stored in the variables `number1` and `number2`. In the preceding statement, the addition operator is a *binary operator*—its *two* operands are the variables `number1` and `number2`. Portions of statements that contain calculations are called **expressions**. In fact, an expression is any portion of a statement that has a *value* associated with it. For example, the value of the expression `number1 + number2` is the *sum* of the numbers. Similarly, the value of the expression `input.nextInt()` is the integer typed by the user.

### Displaying the Result of the Calculation

After the calculation has been performed, line 25

```
System.out.printf( "Sum is %d\n", sum ); // display sum
```

uses method `System.out.printf` to display the sum. The format specifier `%d` is a placeholder for an `int` value (in this case the value of `sum`)—the letter `d` stands for “decimal integer.” The remaining characters in the format string are all fixed text. So, method `printf` displays “Sum is ”, followed by the value of `sum` (in the position of the `%d` format specifier) and a newline.

Calculations can also be performed *inside* `printf` statements. We could have combined the statements at lines 23 and 25 into the statement

```
System.out.printf( "Sum is %d\n", ( number1 + number2 ) );
```

The parentheses around the expression `number1 + number2` are not required—they're included to emphasize that the value of the *entire* expression is output in the position of the `%d` format specifier.

### Java API Documentation

For each new Java API class we use, we indicate the package in which it's located. This information helps you locate descriptions of each package and class in the Java API documentation. A web-based version of this documentation can be found at

```
download.oracle.com/javase/6/docs/api/
```

You can download it from

```
www.oracle.com/technetwork/java/javase/downloads/index.html
```

Appendix E shows how to use this documentation.

## 2.6 Memory Concepts

Variable names such as `number1`, `number2` and `sum` actually correspond to locations in the computer's memory. Every variable has a **name**, a **type**, a **size** (in bytes) and a **value**.

In the addition program of Fig. 2.7, when the following statement (line 18) executes:

```
number1 = input.nextInt(); // read first number from user
```

the number typed by the user is placed into a memory location corresponding to the name `number1`. Suppose that the user enters 45. The computer places that integer value into location `number1` (Fig. 2.8), replacing the previous value (if any) in that location. The previous value is lost.

---

number1	45
---------	----

---

**Fig. 2.8** | Memory location showing the name and value of variable `number1`.

When the statement (line 21)

```
number2 = input.nextInt(); // read second number from user
```

executes, suppose that the user enters 72. The computer places that integer value into location `number2`. The memory now appears as shown in Fig. 2.9.

---

number1	45
number2	72

---

**Fig. 2.9** | Memory locations after storing values for `number1` and `number2`.

After the program of Fig. 2.7 obtains values for `number1` and `number2`, it adds the values and places the total into variable `sum`. The statement (line 23)

```
sum = number1 + number2; // add numbers, then store total in sum
```

performs the addition, then replaces any previous value in `sum`. After `sum` has been calculated, memory appears as shown in Fig. 2.10. The values of `number1` and `number2` appear exactly as they did before they were used in the calculation of `sum`. These values were used, but not destroyed, as the computer performed the calculation. When a value is read from a memory location, the process is nondestructive.

number1	45
number2	72
sum	117

**Fig. 2.10** | Memory locations after storing the sum of `number1` and `number2`.

## 2.7 Arithmetic

Most programs perform arithmetic calculations. The **arithmetic operators** are summarized in Fig. 2.11. Note the use of various special symbols not used in algebra. The **asterisk** (\*) indicates multiplication, and the percent sign (%) is the **remainder operator**, which we'll discuss shortly. The arithmetic operators in Fig. 2.11 are *binary* operators, because each operates on *two* operands. For example, the expression `f + 7` contains the binary operator `+` and the two operands `f` and `7`.

Java operation	Operator	Algebraic expression	Java expression
Addition	<code>+</code>	$f + 7$	<code>f + 7</code>
Subtraction	<code>-</code>	$p - c$	<code>p - c</code>
Multiplication	<code>*</code>	$bm$	<code>b * m</code>
Division	<code>/</code>	$x / y$ or $\frac{x}{y}$ or $x \div y$	<code>x / y</code>
Remainder	<code>%</code>	$r \bmod s$	<code>r % s</code>

**Fig. 2.11** | Arithmetic operators.

**Integer division** yields an integer quotient. For example, the expression `7 / 4` evaluates to 1, and the expression `17 / 5` evaluates to 3. Any fractional part in integer division is simply *discarded* (i.e., *truncated*)—no rounding occurs. Java provides the remainder operator, `%`, which yields the remainder after division. The expression `x % y` yields the remainder after `x` is divided by `y`. Thus, `7 % 4` yields 3, and `17 % 5` yields 2. This operator is most commonly used with integer operands but can also be used with other arithmetic types. In this chapter's exercises and in later chapters, we consider several interesting applications of the remainder operator, such as determining whether one number is a multiple of another.

*Arithmetic Expressions in Straight-Line Form*

Arithmetic expressions in Java must be written in **straight-line form** to facilitate entering programs into the computer. Thus, expressions such as “a divided by b” must be written as  $a / b$ , so that all constants, variables and operators appear in a straight line. The following algebraic notation is generally not acceptable to compilers:

$$\frac{a}{b}$$

*Parentheses for Grouping Subexpressions*

Parentheses are used to group terms in Java expressions in the same manner as in algebraic expressions. For example, to multiply a times the quantity  $b + c$ , we write

$$a * ( b + c )$$

If an expression contains **nested parentheses**, such as

$$( ( a + b ) * c )$$

the expression in the innermost set of parentheses ( $a + b$  in this case) is evaluated first.

*Rules of Operator Precedence*

Java applies the operators in arithmetic expressions in a precise sequence determined by the **rules of operator precedence**, which are generally the same as those followed in algebra:

1. Multiplication, division and remainder operations are applied first. If an expression contains several such operations, they’re applied from left to right. Multiplication, division and remainder operators have the same level of precedence.
2. Addition and subtraction operations are applied next. If an expression contains several such operations, the operators are applied from left to right. Addition and subtraction operators have the same level of precedence.

These rules enable Java to apply operators in the correct order.<sup>1</sup> When we say that operators are applied from left to right, we’re referring to their **associativity**. Some operators associate from right to left. Figure 2.12 summarizes these rules of operator precedence. A complete precedence chart is included in Appendix A.

Operator(s)	Operation(s)	Order of evaluation (precedence)
* / %	Multiplication Division Remainder	Evaluated first. If there are several operators of this type, they’re evaluated from left to right.
+ -	Addition Subtraction	Evaluated next. If there are several operators of this type, they’re evaluated from left to right.
=	Assignment	Evaluated last.

**Fig. 2.12** | Precedence of arithmetic operators.

1. We use simple examples to explain the order of evaluation of expressions. Subtle issues occur in the more complex expressions you’ll encounter later in the book. For more information on order of evaluation, see Chapter 15 of *The Java™ Language Specification* ([java.sun.com/docs/books/jls/](http://java.sun.com/docs/books/jls/)).

### Sample Algebraic and Java Expressions

Now let's consider several expressions in light of the rules of operator precedence. Each example lists an algebraic expression and its Java equivalent. The following is an example of an arithmetic mean (average) of five terms:

$$\begin{array}{ll} \text{Algebra:} & m = \frac{a + b + c + d + e}{5} \\ \text{Java:} & m = ( a + b + c + d + e ) / 5; \end{array}$$

The parentheses are required because division has higher precedence than addition. The entire quantity  $(a + b + c + d + e)$  is to be divided by 5. If the parentheses are erroneously omitted, we obtain  $a + b + c + d + e / 5$ , which evaluates as

$$a + b + c + d + \frac{e}{5}$$

Here's an example of the equation of a straight line:

$$\begin{array}{ll} \text{Algebra:} & y = mx + b \\ \text{Java:} & y = m * x + b; \end{array}$$

No parentheses are required. The multiplication operator is applied first because multiplication has a higher precedence than addition. The assignment occurs last because it has a lower precedence than multiplication or addition.

The following example contains remainder (%), multiplication, division, addition and subtraction operations:

$$\begin{array}{ll} \text{Algebra:} & z = pr \% q + w/x - y \\ \text{Java:} & z = p * r \% q + w / x - y; \end{array}$$

The circled numbers under the statement indicate the order in which Java applies the operators. The \*, % and / operations are evaluated first in left-to-right order (i.e., they associate from left to right), because they have higher precedence than + and -. The + and - operations are evaluated next. These operations are also applied from left to right. The assignment (=) operator is evaluated last.

### Evaluation of a Second-Degree Polynomial

To develop a better understanding of the rules of operator precedence, consider the evaluation of an assignment expression that includes a second-degree polynomial  $ax^2 + bx + c$ :

$$y = a * x * x + b * x + c;$$

The multiplication operations are evaluated first in left-to-right order (i.e., they associate from left to right), because they have higher precedence than addition. (Java has no arithmetic operator for exponentiation in Java, so  $x^2$  is represented as  $x * x$ . Section 5.4 shows an alternative for performing exponentiation.) The addition operations are evaluated next from left to right. Suppose that  $a$ ,  $b$ ,  $c$  and  $x$  are initialized (given values) as follows:  $a = 2$ ,  $b = 3$ ,  $c = 7$  and  $x = 5$ . Figure 2.13 illustrates the order in which the operators are applied.

**Fig. 2.13** | Order in which a second-degree polynomial is evaluated.

You can use **redundant parentheses** (unnecessary parentheses) to make an expression clearer. For example, the preceding statement might be parenthesized as follows:

```
y = ( a * x * x ) + ( b * x ) + c;
```

## 2.8 Decision Making: Equality and Relational Operators

A **condition** is an expression that can be **true** or **false**. This section introduces Java’s **if selection statement**, which allows a program to make a **decision** based on a condition’s value. For example, the condition “grade is greater than or equal to 60” determines whether a student passed a test. If the condition in an **if** statement is true, the body of the **if** statement executes. If the condition is false, the body does not execute. We’ll see an example shortly.

Conditions in **if** statements can be formed by using the **equality operators** (**==** and **!=**) and **relational operators** (**>**, **<**, **>=** and **<=**) summarized in Fig. 2.14. Both equality operators have the same level of precedence, which is *lower* than that of the relational operators. The equality operators associate from left to right. The relational operators all have the same level of precedence and also associate from left to right.

Figure 2.15 uses six **if** statements to compare two integers input by the user. If the condition in any of these **if** statements is true, the statement associated with that **if** statement executes; otherwise, the statement is skipped. We use a **Scanner** to input the integers from the user and store them in variables **number1** and **number2**. The program compares the numbers and displays the results of the comparisons that are true.

Standard algebraic equality or relational operator	Java equality or relational operator	Sample Java condition	Meaning of Java condition
<i>Equality operators</i>			
=	==	x == y	x is equal to y
≠	!=	x != y	x is not equal to y
<i>Relational operators</i>			
>	>	x > y	x is greater than y
<	<	x < y	x is less than y
≥	>=	x >= y	x is greater than or equal to y
≤	<=	x <= y	x is less than or equal to y

**Fig. 2.14** | Equality and relational operators.

```

1 // Fig. 2.15: Comparison.java
2 // Compare integers using if statements, relational operators
3 // and equality operators.
4 import java.util.Scanner; // program uses class Scanner
5
6 public class Comparison
7 {
8     // main method begins execution of Java application
9     public static void main( String[] args )
10    {
11        // create Scanner to obtain input from command line
12        Scanner input = new Scanner( System.in );
13
14        int number1; // first number to compare
15        int number2; // second number to compare
16
17        System.out.print( "Enter first integer: " ); // prompt
18        number1 = input.nextInt(); // read first number from user
19
20        System.out.print( "Enter second integer: " ); // prompt
21        number2 = input.nextInt(); // read second number from user
22
23        if ( number1 == number2 )
24            System.out.printf( "%d == %d\n", number1, number2 );
25
26        if ( number1 != number2 )
27            System.out.printf( "%d != %d\n", number1, number2 );
28
29        if ( number1 < number2 )
30            System.out.printf( "%d < %d\n", number1, number2 );
31

```

**Fig. 2.15** | Compare integers using if statements, relational operators and equality operators. (Part I of 2.)

```

32     if ( number1 > number2 )
33         System.out.printf( "%d > %d\n", number1, number2 );
34
35     if ( number1 <= number2 )
36         System.out.printf( "%d <= %d\n", number1, number2 );
37
38     if ( number1 >= number2 )
39         System.out.printf( "%d >= %d\n", number1, number2 );
40     } // end method main
41 } // end class Comparison

```

```

Enter first integer: 777
Enter second integer: 777
777 == 777
777 <= 777
777 >= 777

```

```

Enter first integer: 1000
Enter second integer: 2000
1000 != 2000
1000 < 2000
1000 <= 2000

```

```

Enter first integer: 2000
Enter second integer: 1000
2000 != 1000
2000 > 1000
2000 >= 1000

```

**Fig. 2.15** | Compare integers using `if` statements, relational operators and equality operators. (Part 2 of 2.)

The declaration of class `Comparison` begins at line 6

```
public class Comparison
```

The class's main method (lines 9–40) begins the execution of the program. Line 12

```
Scanner input = new Scanner( System.in );
```

declares `Scanner` variable `input` and assigns it a `Scanner` that inputs data from the standard input (i.e., the keyboard).

Lines 14–15

```
int number1; // first number to compare
int number2; // second number to compare
```

declare the `int` variables used to store the values input from the user.

Lines 17–18

```
System.out.print( "Enter first integer: " ); // prompt
number1 = input.nextInt(); // read first number from user
```

prompt the user to enter the first integer and input the value, respectively. The input value is stored in variable `number1`.

Lines 20–21

```
System.out.print( "Enter second integer: " ); // prompt
number2 = input.nextInt(); // read second number from user
```

prompt the user to enter the second integer and input the value, respectively. The input value is stored in variable `number2`.

Lines 23–24

```
if ( number1 == number2 )
    System.out.printf( "%d == %d\n", number1, number2 );
```

compare the values of `number1` and `number2` to determine whether they're equal. An `if` statement always begins with keyword `if`, followed by a condition in parentheses. An `if` statement expects one statement in its body, but may contain multiple statements if they're enclosed in a set of braces (`{}`). The indentation of the body statement shown here is not required, but it improves the program's readability by emphasizing that the statement in line 24 *is part of* the `if` statement that begins at line 23. Line 24 executes only if the numbers stored in variables `number1` and `number2` are equal (i.e., the condition is true). The `if` statements in lines 26–27, 29–30, 32–33, 35–36 and 38–39 compare `number1` and `number2` using the operators `!=`, `<`, `>`, `<=` and `>=`, respectively. If the condition in one or more of the `if` statements is true, the corresponding body statement executes.

### Common Programming Error 2.6

*Confusing the equality operator, `==`, with the assignment operator, `=`, can cause a logic error or a syntax error. The equality operator should be read as “is equal to” and the assignment operator as “gets” or “gets the value of.” To avoid confusion, some people read the equality operator as “double equals” or “equals equals.”*

### Good Programming Practice 2.11

*Placing only one statement per line in a program enhances program readability.*

There's no semicolon (`;`) at the end of the first line of each `if` statement. Such a semicolon would result in a logic error at execution time. For example,

```
if ( number1 == number2 ); // logic error
    System.out.printf( "%d == %d\n", number1, number2 );
```

would actually be interpreted by Java as

```
if ( number1 == number2 )
    ; // empty statement
    System.out.printf( "%d == %d\n", number1, number2 );
```

where the semicolon on the line by itself—called the **empty statement**—is the statement to execute if the condition in the `if` statement is true. When the empty statement executes, no task is performed. The program then continues with the output statement, which always executes, regardless of whether the condition is true or false, because the output statement is not part of the `if` statement.

### Common Programming Error 2.7

*Placing a semicolon immediately after the right parenthesis of the condition in an `if` statement is normally a logic error.*

Note the use of white space in Fig. 2.15. Recall that the compiler normally ignores white space. So, statements may be split over several lines and may be spaced according to your preferences without affecting a program's meaning. It's incorrect to split identifiers and strings. Ideally, statements should be kept small, but this is not always possible.

### Error-Prevention Tip 2.9

*A lengthy statement can be spread over several lines. If a single statement must be split across lines, choose breaking points that make sense, such as after a comma in a comma-separated list, or after an operator in a lengthy expression. If a statement is split across two or more lines, indent all subsequent lines until the end of the statement.*

Figure 2.16 shows the operators discussed so far in decreasing order of precedence. All but the assignment operator, `=`, associate from left to right. The assignment operator, `=`, associates from right to left, so an expression like `x = y = 0` is evaluated as if it had been written as `x = (y = 0)`, which first assigns the value 0 to variable `y`, then assigns the result of that assignment, 0, to `x`.

### Good Programming Practice 2.12

*When writing expressions containing many operators, refer to the operator precedence chart (Appendix A). Confirm that the operations in the expression are performed in the order you expect. If, in a complex expression, you're uncertain about the order of evaluation, use parentheses to force the order, exactly as you'd do in algebraic expressions.*

Operators	Associativity	Type
* / %	left to right	multiplicative
+ -	left to right	additive
< <= > >=	left to right	relational
== !=	left to right	equality
=	right to left	assignment

**Fig. 2.16** | Precedence and associativity of operators discussed.

## 2.9 Wrap-Up

In this chapter, you learned many important features of Java, including displaying data on the screen in a **Command Prompt**, inputting data from the keyboard, performing calculations and making decisions. The applications presented here introduced you to basic programming concepts. As you'll see in Chapter 3, Java applications typically contain just a few lines of code in method `main`—these statements normally create the objects that perform the work of the application. In Chapter 3, you'll learn how to implement your own classes and use objects of those classes in applications.

## Summary

### Section 2.2 Your First Program in Java: Printing a Line of Text

- A Java application (p. 38) executes when you use the `java` command to launch the JVM.

- Comments (p. 39) document programs and improve their readability. The compiler ignores them.
- A comment that begins with `//` is an end-of-line comment—it terminates at the end of the line on which it appears.
- Traditional comments (p. 39) can be spread over several lines and are delimited by `/*` and `*/`.
- Javadoc comments (p. 39), delimited by `/**` and `*/`, enable you to embed program documentation in your code. The javadoc utility program generates HTML pages based on these comments.
- A syntax error (p. 39; also called a compiler error, compile-time error or compilation error) occurs when the compiler encounters code that violates Java’s language rules. It’s similar to a grammar error in a natural language.
- Blank lines, space characters and tab characters are known as white space (p. 39). White space makes programs easier to read and is ignored by the compiler.
- Keywords (p. 40) are reserved for use by Java and are always spelled with all lowercase letters.
- Keyword `class` (p. 40) introduces a class declaration.
- By convention, all class names in Java begin with a capital letter and capitalize the first letter of each word they include (e.g., `SampleClassName`).
- A Java class name is an identifier—a series of characters consisting of letters, digits, underscores (`_`) and dollar signs (`$`) that does not begin with a digit and does not contain spaces.
- Java is case sensitive (p. 40)—that is, uppercase and lowercase letters are distinct.
- The body of every class declaration (p. 40) is delimited by braces, `{` and `}`.
- A `public` (p. 40) class declaration must be saved in a file with the same name as the class followed by the “.java” file-name extension.
- Method `main` (p. 41) is the starting point of every Java application and must begin with
 

```
public static void main( String[] args )
```

 otherwise, the JVM will not execute the application.
- Methods perform tasks and return information when they complete them. Keyword `void` (p. 41) indicates that a method will perform a task but return no information.
- Statements instruct the computer to perform actions.
- A string (p. 41) in double quotes is sometimes called a character string or a string literal.
- The standard output object (`System.out`; p. 41) displays characters in the command window.
- Method `System.out.println` (p. 41) displays its argument (p. 41) in the command window followed by a newline character to position the output cursor to the beginning of the next line.
- You compile a program with the command `javac`. If the program contains no syntax errors, a class file (p. 43) containing the Java bytecodes that represent the application is created. These bytecodes are interpreted by the JVM when you execute the program.
- To run an application, type `java` (p. 38) followed by the name of the class that contains `main`.

### Section 2.3 Modifying Your First Java Program

- `System.out.print` (p. 44) displays its argument and positions the output cursor immediately after the last character displayed.
- A backslash (`\`) in a string is an escape character (p. 45). Java combines it with the next character to form an escape sequence (p. 45). The escape sequence `\n` (p. 45) represents the newline character.

### Section 2.4 Displaying Text with `printf`

- `System.out.printf` method (p. 46; `f` means “formatted”) displays formatted data.

- Method `printf`'s first argument is a format string (p. 47) containing fixed text and/or format specifiers. Each format specifier (p. 47) indicates the type of data to output and is a placeholder for a corresponding argument that appears after the format string.
- Format specifiers begin with a percent sign (%) and are followed by a character that represents the data type. The format specifier `%s` (p. 47) is a placeholder for a string.

### Section 2.5 Another Application: Adding Integers

- An `import` declaration (p. 48) helps the compiler locate a class that's used in a program.
- Java's rich set of predefined classes are grouped into packages (p. 48)—named groups of classes. These are referred to as the Java class library (p. 48), or the Java Application Programming Interface (Java API).
- A variable (p. 49) is a location in the computer's memory where a value can be stored for use later in a program. All variables must be declared with a name and a type before they can be used.
- A variable's name enables the program to access the variable's value in memory.
- A `Scanner` (package `java.util`; p. 49) enables a program to read data that the program will use. Before a `Scanner` can be used, the program must create it and specify the source of the data.
- Variables should be initialized (p. 49) to prepare them for use in a program.
- The expression `new Scanner(System.in)` creates a `Scanner` that reads from the standard input object (`System.in`; p. 49)—normally the keyboard.
- Data type `int` (p. 49) is used to declare variables that will hold integer values. The range of values for an `int` is `-2,147,483,648` to `+2,147,483,647`.
- Types `float` and `double` (p. 49) specify real numbers with decimal points, such as `3.4` and `-11.19`.
- Variables of type `char` (p. 49) represent individual characters, such as an uppercase letter (e.g., `A`), a digit (e.g., `7`), a special character (e.g., `*` or `%`) or an escape sequence (e.g., `\n`, `\n`).
- Types such as `int`, `float`, `double` and `char` are primitive types (p. 49). Primitive-type names are keywords; thus, they must appear in all lowercase letters.
- A prompt (p. 50) directs the user to take a specific action.
- `Scanner` method `nextInt` obtains an integer for use in a program.
- The assignment operator, `=` (p. 51), enables the program to give a value to a variable. It's called a binary operator (p. 51) because it has two operands.
- Portions of statements that have values are called expressions (p. 51).
- The format specifier `%d` (p. 51) is a placeholder for an `int` value.

### Section 2.6 Memory Concepts

- Variable names (p. 52) correspond to locations in the computer's memory. Every variable has a name, a type, a size and a value.
- A value that's placed in a memory location replaces the location's previous value, which is lost.

### Section 2.7 Arithmetic

- The arithmetic operators (p. 53) are `+` (addition), `-` (subtraction), `*` (multiplication), `/` (division) and `%` (remainder).
- Integer division (p. 53) yields an integer quotient.
- The remainder operator, `%` (p. 53), yields the remainder after division.
- Arithmetic expressions must be written in straight-line form (p. 54).
- If an expression contains nested parentheses (p. 54), the innermost set is evaluated first.

- Java applies the operators in arithmetic expressions in a precise sequence determined by the rules of operator precedence (p. 54).
- When we say that operators are applied from left to right, we're referring to their associativity (p. 54). Some operators associate from right to left.
- Redundant parentheses (p. 56) can make an expression clearer.

### Section 2.8 Decision Making: Equality and Relational Operators

- The `if` statement (p. 56) makes a decision based on a condition's value (true or false).
- Conditions in `if` statements can be formed by using the equality (`==` and `!=`) and relational (`>`, `<`, `>=` and `<=`) operators (p. 56).
- An `if` statement begins with keyword `if` followed by a condition in parentheses and expects one statement in its body.
- The empty statement (p. 59) is a statement that does not perform a task.

## Self-Review Exercises

- 2.1** Fill in the blanks in each of the following statements:
- A(n) \_\_\_\_\_ begins the body of every method, and a(n) \_\_\_\_\_ ends the body of every method.
  - The \_\_\_\_\_ statement is used to make decisions.
  - \_\_\_\_\_ begins an end-of-line comment.
  - \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_ are called white space.
  - \_\_\_\_\_ are reserved for use by Java.
  - Java applications begin execution at method \_\_\_\_\_.
  - Methods \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_ display information in a command window.
- 2.2** State whether each of the following is *true* or *false*. If *false*, explain why.
- Comments cause the computer to print the text after the `//` on the screen when the program executes.
  - All variables must be given a type when they're declared.
  - Java considers the variables `number` and `NUMBER` to be identical.
  - The remainder operator (`%`) can be used only with integer operands.
  - The arithmetic operators `*`, `/`, `%`, `+` and `-` all have the same level of precedence.
- 2.3** Write statements to accomplish each of the following tasks:
- Declare variables `c`, `thisIsAVariable`, `q76354` and `number` to be of type `int`.
  - Prompt the user to enter an integer.
  - Input an integer and assign the result to `int` variable `value`. Assume `Scanner` variable `input` can be used to read a value from the keyboard.
  - Print "This is a Java program" on one line in the command window. Use method `System.out.println`.
  - Print "This is a Java program" on two lines in the command window. The first line should end with `Java`. Use method `System.out.println`.
  - Print "This is a Java program" on two lines in the command window. The first line should end with `Java`. Use method `System.out.printf` and two `%s` format specifiers.
  - If the variable `number` is not equal to 7, display "The variable number is not equal to 7".
- 2.4** Identify and correct the errors in each of the following statements:
- ```
if ( c < 7 );
    System.out.println( "c is less than 7" );
```
  - ```
if ( c => 7 )
    System.out.println( "c is equal to or greater than 7" );
```

**2.5** Write declarations, statements or comments that accomplish each of the following tasks:

- a) State that a program will calculate the product of three integers.
- b) Create a Scanner called `input` that reads values from the standard input.
- c) Declare the variables `x`, `y`, `z` and `result` to be of type `int`.
- d) Prompt the user to enter the first integer.
- e) Read the first integer from the user and store it in the variable `x`.
- f) Prompt the user to enter the second integer.
- g) Read the second integer from the user and store it in the variable `y`.
- h) Prompt the user to enter the third integer.
- i) Read the third integer from the user and store it in the variable `z`.
- j) Compute the product of the three integers contained in variables `x`, `y` and `z`, and assign the result to the variable `result`.
- k) Display the message "Product is" followed by the value of the variable `result`.

**2.6** Using the statements you wrote in Exercise 2.5, write a complete program that calculates and prints the product of three integers.

## Answers to Self-Review Exercises

**2.1** a) left brace (`{`), right brace (`}`). b) `if`. c) `//`. d) Space characters, newlines and tabs. e) Keywords. f) `main`. g) `System.out.print`, `System.out.println` and `System.out.printf`.

**2.2** a) False. Comments do not cause any action to be performed when the program executes. They're used to document programs and improve their readability.  
 b) True.  
 c) False. Java is case sensitive, so these variables are distinct.  
 d) False. The remainder operator can also be used with noninteger operands in Java.  
 e) False. The operators `*`, `/` and `%` are higher precedence than operators `+` and `-`.

**2.3** a) 

```
int c, thisIsAVariable, q76354, number;
or
int c;
int thisIsAVariable;
int q76354;
int number;
```

 b) 

```
System.out.print( "Enter an integer: " );
```

 c) 

```
value = input.nextInt();
```

 d) 

```
System.out.println( "This is a Java program" );
```

 e) 

```
System.out.println( "This is a Java\nprogram" );
```

 f) 

```
System.out.printf( "%s\n%s\n", "This is a Java", "program" );
```

 g) 

```
if ( number != 7 )
    System.out.println( "The variable number is not equal to 7" );
```

**2.4** a) Error: Semicolon after the right parenthesis of the condition (`c < 7`) in the `if`.  
 Correction: Remove the semicolon after the right parenthesis. [Note: As a result, the output statement will execute regardless of whether the condition in the `if` is true.]

b) Error: The relational operator `=>` is incorrect. Correction: Change `=>` to `>=`.

**2.5** a) 

```
// Calculate the product of three integers
```

  
 b) 

```
Scanner input = new Scanner( System.in );
```

  
 c) 

```
int x, y, z, result;
```

  
 or

```

    int x;
    int y;
    int z;
    int result;
d) System.out.print( "Enter first integer: " );
e) x = input.nextInt();
f) System.out.print( "Enter second integer: " );
g) y = input.nextInt();
h) System.out.print( "Enter third integer: " );
i) z = input.nextInt();
j) result = x * y * z;
k) System.out.printf( "Product is %d\n", result );

```

**2.6** The solution to Self-Review Exercise 2.6 is as follows:

```

1 // Ex. 2.6: Product.java
2 // Calculate the product of three integers.
3 import java.util.Scanner; // program uses Scanner
4
5 public class Product
6 {
7     public static void main( String[] args )
8     {
9         // create Scanner to obtain input from command window
10        Scanner input = new Scanner( System.in );
11
12        int x; // first number input by user
13        int y; // second number input by user
14        int z; // third number input by user
15        int result; // product of numbers
16
17        System.out.print( "Enter first integer: " ); // prompt for input
18        x = input.nextInt(); // read first integer
19
20        System.out.print( "Enter second integer: " ); // prompt for input
21        y = input.nextInt(); // read second integer
22
23        System.out.print( "Enter third integer: " ); // prompt for input
24        z = input.nextInt(); // read third integer
25
26        result = x * y * z; // calculate product of numbers
27
28        System.out.printf( "Product is %d\n", result );
29    } // end method main
30 } // end class Product

```

```

Enter first integer: 10
Enter second integer: 20
Enter third integer: 30
Product is 6000

```

## Exercises

**2.7** Fill in the blanks in each of the following statements:

- \_\_\_\_\_ are used to document a program and improve its readability.
- A decision can be made in a Java program with a(n) \_\_\_\_\_.

- c) Calculations are normally performed by \_\_\_\_\_ statements.
- d) The arithmetic operators with the same precedence as multiplication are \_\_\_\_\_ and \_\_\_\_\_.
- e) When parentheses in an arithmetic expression are nested, the \_\_\_\_\_ set of parentheses is evaluated first.
- f) A location in the computer's memory that may contain different values at various times throughout the execution of a program is called a(n) \_\_\_\_\_.
- 2.8** Write Java statements that accomplish each of the following tasks:
- Display the message "Enter an integer: ", leaving the cursor on the same line.
  - Assign the product of variables b and c to variable a.
  - Use a comment to state that a program performs a sample payroll calculation.
- 2.9** State whether each of the following is *true* or *false*. If *false*, explain why.
- Java operators are evaluated from left to right.
  - The following are all valid variable names: `_under_bar_`, `m928134`, `t5`, `j7`, `her_sales$`, `his_$account_total`, `a`, `b$`, `c`, `z` and `z2`.
  - A valid Java arithmetic expression with no parentheses is evaluated from left to right.
  - The following are all invalid variable names: `3g`, `87`, `67h2`, `h22` and `2h`.
- 2.10** Assuming that  $x = 2$  and  $y = 3$ , what does each of the following statements display?
- `System.out.printf( "x = %d\n", x );`
  - `System.out.printf( "Value of %d + %d is %d\n", x, x, ( x + x ) );`
  - `System.out.printf( "x = " );`
  - `System.out.printf( "%d = %d\n", ( x + y ), ( y + x ) );`
- 2.11** Which of the following Java statements contain variables whose values are modified?
- `p = i + j + k + 7;`
  - `System.out.println( "variables whose values are modified" );`
  - `System.out.println( "a = 5" );`
  - `value = input.nextInt();`
- 2.12** Given that  $y = ax^3 + 7$ , which of the following are correct Java statements for this equation?
- `y = a * x * x * x + 7;`
  - `y = a * x * x * ( x + 7 );`
  - `y = ( a * x ) * x * ( x + 7 );`
  - `y = ( a * x ) * x * x + 7;`
  - `y = a * ( x * x * x ) + 7;`
  - `y = a * x * ( x * x + 7 );`
- 2.13** State the order of evaluation of the operators in each of the following Java statements, and show the value of x after each statement is performed:
- `x = 7 + 3 * 6 / 2 - 1;`
  - `x = 2 % 2 + 2 * 2 - 2 / 2;`
  - `x = ( 3 * 9 * ( 3 + ( 9 * 3 / ( 3 ) ) ) );`
- 2.14** Write an application that displays the numbers 1 to 4 on the same line, with each pair of adjacent numbers separated by one space. Use the following techniques:
- Use one `System.out.println` statement.
  - Use four `System.out.print` statements.
  - Use one `System.out.printf` statement.
- 2.15** (*Arithmetic*) Write an application that asks the user to enter two integers, obtains them from the user and prints their sum, product, difference and quotient (division). Use the techniques shown in Fig. 2.7.

**2.16** (*Comparing Integers*) Write an application that asks the user to enter two integers, obtains them from the user and displays the larger number followed by the words "is larger". If the numbers are equal, print the message "These numbers are equal". Use the techniques shown in Fig. 2.15.

**2.17** (*Arithmetic, Smallest and Largest*) Write an application that inputs three integers from the user and displays the sum, average, product, smallest and largest of the numbers. Use the techniques shown in Fig. 2.15. [Note: The calculation of the average in this exercise should result in an integer representation of the average. So, if the sum of the values is 7, the average should be 2, not 2.3333....]

**2.18** (*Displaying Shapes with Asterisks*) Write an application that displays a box, an oval, an arrow and a diamond using asterisks (\*), as follows:

```

*****      ***      *      *
*      *  *      *      ***      *  *
*      *  *      *      *****      *  *
*      *  *      *      *      *      *
*      *  *      *      *      *      *
*      *  *      *      *      *      *
*      *  *      *      *      *      *
*      *  *      *      *      *      *
*****      ***      *      *

```

**2.19** What does the following code print?

```
System.out.println( "*" + "\n*" + "\n***" + "\n*****" );
```

**2.20** What does the following code print?

```
System.out.println( "*" );
System.out.println( "****" );
System.out.println( "*****" );
System.out.println( "*****" );
System.out.println( "****" );
```

**2.21** What does the following code print?

```
System.out.print( "*" );
System.out.print( "****" );
System.out.print( "*****" );
System.out.print( "*****" );
System.out.println( "****" );
```

**2.22** What does the following code print?

```
System.out.print( "*" );
System.out.println( "****" );
System.out.println( "*****" );
System.out.print( "*****" );
System.out.println( "****" );
```

**2.23** What does the following code print?

```
System.out.printf( "%s\n%s\n%s\n", "*", "****", "*****" );
```

**2.24** (*Largest and Smallest Integers*) Write an application that reads five integers and determines and prints the largest and smallest integers in the group. Use only the programming techniques you learned in this chapter.

**2.25** (*Odd or Even*) Write an application that reads an integer and determines and prints whether it's odd or even. [Hint: Use the remainder operator. An even number is a multiple of 2. Any multiple of 2 leaves a remainder of 0 when divided by 2.]

**2.26** (*Multiples*) Write an application that reads two integers, determines whether the first is a multiple of the second and prints the result. [*Hint*: Use the remainder operator.]

**2.27** (*Checkerboard Pattern of Asterisks*) Write an application that displays a checkerboard pattern, as follows:

```
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
```

**2.28** (*Diameter, Circumference and Area of a Circle*) Here's a peek ahead. In this chapter, you learned about integers and the type `int`. Java can also represent floating-point numbers that contain decimal points, such as 3.14159. Write an application that inputs from the user the radius of a circle as an integer and prints the circle's diameter, circumference and area using the floating-point value 3.14159 for  $\pi$ . Use the techniques shown in Fig. 2.7. [*Note*: You may also use the predefined constant `Math.PI` for the value of  $\pi$ . This constant is more precise than the value 3.14159. Class `Math` is defined in package `java.lang`. Classes in that package are imported automatically, so you do not need to `import class Math` to use it.] Use the following formulas ( $r$  is the radius):

$$\begin{aligned} \text{diameter} &= 2r \\ \text{circumference} &= 2\pi r \\ \text{area} &= \pi r^2 \end{aligned}$$

Do not store the results of each calculation in a variable. Rather, specify each calculation as the value that will be output in a `System.out.printf` statement. The values produced by the circumference and area calculations are floating-point numbers. Such values can be output with the format specifier `%f` in a `System.out.printf` statement. You'll learn more about floating-point numbers in Chapter 3.

**2.29** (*Integer Value of a Character*) Here's another peek ahead. In this chapter, you learned about integers and the type `int`. Java can also represent uppercase letters, lowercase letters and a considerable variety of special symbols. Every character has a corresponding integer representation. The set of characters a computer uses together with the corresponding integer representations for those characters is called that computer's character set. You can indicate a character value in a program simply by enclosing that character in single quotes, as in `'A'`.

You can determine a character's integer equivalent by preceding that character with `(int)`, as in

```
(int) 'A'
```

An operator of this form is called a cast operator. (You'll learn about cast operators in Chapter 4.) The following statement outputs a character and its integer equivalent:

```
System.out.printf(
    "The character %c has the value %d\n", 'A', (int) 'A' );
```

When the preceding statement executes, it displays the character `A` and the value 65 (from the Unicode® character set) as part of the string. The format specifier `%c` is a placeholder for a character (in this case, the character `'A'`).

Using statements similar to the one shown earlier in this exercise, write an application that displays the integer equivalents of some uppercase letters, lowercase letters, digits and special symbols. Display the integer equivalents of the following: `A B C a b c 0 1 2 $ * + /` and the blank character.

**2.30** (*Separating the Digits in an Integer*) Write an application that inputs one number consisting of five digits from the user, separates the number into its individual digits and prints the digits separated from one another by three spaces each. For example, if the user types in the number 42339, the program should print

```
4 2 3 3 9
```

Assume that the user enters the correct number of digits. What happens when you execute the program and type a number with more than five digits? What happens when you execute the program and type a number with fewer than five digits? [*Hint:* It’s possible to do this exercise with the techniques you learned in this chapter. You’ll need to use both division and remainder operations to “pick off” each digit.]

**2.31** (*Table of Squares and Cubes*) Using only the programming techniques you learned in this chapter, write an application that calculates the squares and cubes of the numbers from 0 to 10 and prints the resulting values in table format, as shown below. [*Note:* This program does not require any input from the user.]

number	square	cube
0	0	0
1	1	1
2	4	8
3	9	27
4	16	64
5	25	125
6	36	216
7	49	343
8	64	512
9	81	729
10	100	1000

**2.32** (*Negative, Positive and Zero Values*) Write a program that inputs five numbers and determines and prints the number of negative numbers input, the number of positive numbers input and the number of zeros input.

## Making a Difference

**2.33** (*Body Mass Index Calculator*) We introduced the body mass index (BMI) calculator in Exercise 1.10. The formulas for calculating BMI are

$$BMI = \frac{weightInPounds \times 703}{heightInInches \times heightInInches}$$

or

$$BMI = \frac{weightInKilograms}{heightInMeters \times heightInMeters}$$

Create a BMI calculator that reads the user’s weight in pounds and height in inches (or, if you prefer, the user’s weight in kilograms and height in meters), then calculates and displays the user’s body mass index. Also, display the following information from the Department of Health and Human Services/National Institutes of Health so the user can evaluate his/her BMI:

BMI VALUES	
Underweight:	less than 18.5
Normal:	between 18.5 and 24.9
Overweight:	between 25 and 29.9
Obese:	30 or greater

[*Note:* In this chapter, you learned to use the `int` type to represent whole numbers. The BMI calculations when done with `int` values will both produce whole-number results. In Chapter 3 you'll learn to use the `double` type to represent numbers with decimal points. When the BMI calculations are performed with `doubles`, they'll both produce numbers with decimal points—these are called “floating-point” numbers.]

**2.34** (*World Population Growth Calculator*) Use the web to determine the current world population and the annual world population growth rate. Write an application that inputs these values, then displays the estimated world population after one, two, three, four and five years.

**2.35** (*Car-Pool Savings Calculator*) Research several car-pooling websites. Create an application that calculates your daily driving cost, so that you can estimate how much money could be saved by car pooling, which also has other advantages such as reducing carbon emissions and reducing traffic congestion. The application should input the following information and display the user's cost per day of driving to work:

- a) Total miles driven per day.
- b) Cost per gallon of gasoline.
- c) Average miles per gallon.
- d) Parking fees per day.
- e) Tolls per day.

# Introduction to Classes, Objects, Methods and Strings

# 3

*Nothing can have value without  
being an object of utility.*

—Karl Marx

*Your public servants serve you  
right.*

—Adlai E. Stevenson

*You'll see something new.  
Two things. And I call them  
Thing One and Thing Two.*

—Dr. Theodor Seuss Geisel

## Objectives

In this chapter you'll learn:

- How to declare a class and use it to create an object.
- How to implement a class's behaviors as methods.
- How to implement a class's attributes as instance variables and properties.
- How to call an object's methods to make them perform their tasks.
- What instance variables of a class and local variables of a method are.
- How to use a constructor to initialize an object's data.
- The differences between primitive and reference types.

Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference

## 3.1 Introduction

We introduced the basic terminology and concepts of object-oriented programming in Section 1.6. In this chapter, we present a simple framework for organizing object-oriented applications in Java. Typically, the applications you develop in this book will consist of two or more classes. If you become part of a development team in industry, you might work on applications that contain hundreds, or even thousands, of classes.

First, we motivate the notion of classes with a real-world example. Then we present five applications to demonstrate creating and using your own classes. The first four of these begin our case study on developing a grade book class that instructors can use to maintain student test scores. This case study is enhanced in Chapters 4, 5 and 7. The last example introduces floating-point numbers—that is, numbers containing decimal points—in a bank account class that maintains a customer’s balance.

## 3.2 Declaring a Class with a Method and Instantiating an Object of a Class

In Sections 2.5 and 2.8, you created an object of the *existing* class `Scanner`, then used that object to read data from the keyboard. In this section, you’ll create a *new* class, then use it to create an object. We begin by declaring classes `GradeBook` (Fig. 3.1) and `GradeBookTest` (Fig. 3.2). Class `GradeBook` (declared in the file `GradeBook.java`) will be used to display a message on the screen (Fig. 3.2) welcoming the instructor to the grade book application. Class `GradeBookTest` (declared in the file `GradeBookTest.java`) is an application class in which the `main` method will create and use an object of class `GradeBook`. *Each class declaration that begins with keyword `public` must be stored in a file having the same name as the class and ending with the `.java` file-name extension.* Thus, classes `GradeBook` and `GradeBookTest` must be declared in *separate* files, because each class is declared `public`.

### Class `GradeBook`

The `GradeBook` class declaration (Fig. 3.1) contains a `displayMessage` method (lines 7–10) that displays a message on the screen. We’ll need to make an object of this class and call its method to execute line 9 and display the message.

The *class declaration* begins in line 4. The keyword `public` is an **access modifier**. For now, we’ll simply declare every class `public`. Every class declaration contains keyword

```
1 // Fig. 3.1: GradeBook.java
2 // Class declaration with one method.
3
4 public class GradeBook
5 {
6     // display a welcome message to the GradeBook user
7     public void displayMessage()
8     {
9         System.out.println( "Welcome to the Grade Book!" );
10    } // end method displayMessage
11 } // end class GradeBook
```

**Fig. 3.1** | Class declaration with one method.

class followed immediately by the class's name. Every class's body is enclosed in a pair of left and right braces, as in lines 5 and 11 of class `GradeBook`.

In Chapter 2, each class we declared had one method named `main`. Class `GradeBook` also has one method—`displayMessage` (lines 7–10). Recall that `main` is a special method that's *always* called automatically by the Java Virtual Machine (JVM) when you execute an application. Most methods do not get called automatically. As you'll soon see, you must call method `displayMessage` explicitly to tell it to perform its task.

The method declaration begins with keyword `public` to indicate that the method is "available to the public"—it can be called from methods of other classes. Next is the method's **return type**, which specifies the type of data the method returns to its caller after performing its task. The return type `void` indicates that this method will perform a task but will *not* return (i.e., give back) any information to its **calling method**. You've used methods that return information—for example, in Chapter 2 you used `Scanner` method `nextInt` to input an integer typed by the user at the keyboard. When `nextInt` reads a value from the user, it returns that value for use in the program.

The name of the method, `displayMessage`, follows the return type. By convention, method names begin with a lowercase first letter and subsequent words in the name begin with a capital letter. The parentheses after the method name indicate that this is a method. Empty parentheses, as in line 7, indicate that this method does not require additional information to perform its task. Line 7 is commonly referred to as the **method header**. Every method's body is delimited by left and right braces, as in lines 8 and 10.

The body of a method contains one or more statements that perform the method's task. In this case, the method contains one statement (line 9) that displays the message "Welcome to the Grade Book!" followed by a newline (because of `println`) in the command window. After this statement executes, the method has completed its task.

### *Class GradeBookTest*

Next, we'd like to use class `GradeBook` in an application. As you learned in Chapter 2, method `main` begins the execution of *every* application. A class that contains method `main` begins the execution of a Java application. Class `GradeBook` is *not* an application because it does *not* contain `main`. Therefore, if you try to execute `GradeBook` by typing `java GradeBook` in the command window, an error will occur. This was not a problem in Chapter 2, because every class you declared had a `main` method. To fix this problem, we must either declare a separate class that contains a `main` method or place a `main` method in class `Grade-`

Book. To help you prepare for the larger programs you'll encounter later in this book and in industry, we use a separate class (`GradeBookTest` in this example) containing method `main` to test each new class we create in this chapter. Some programmers refer to such a class as a *driver class*.

The `GradeBookTest` class declaration (Fig. 3.2) contains the `main` method that will control our application's execution. The `GradeBookTest` class declaration begins in line 4 and ends in line 15. The class, like many that begin an application's execution, contains *only* a `main` method.

```

1 // Fig. 3.2: GradeBookTest.java
2 // Creating a GradeBook object and calling its displayMessage method.
3
4 public class GradeBookTest
5 {
6     // main method begins program execution
7     public static void main( String[] args )
8     {
9         // create a GradeBook object and assign it to myGradeBook
10        GradeBook myGradeBook = new GradeBook();
11
12        // call myGradeBook's displayMessage method
13        myGradeBook.displayMessage();
14    } // end main
15 } // end class GradeBookTest

```

```
Welcome to the Grade Book!
```

**Fig. 3.2** | Creating a `GradeBook` object and calling its `displayMessage` method.

Lines 7–14 declare method `main`. A key part of enabling the JVM to locate and call method `main` to begin the application's execution is the `static` keyword (line 7), which indicates that `main` is a static method. *A static method is special, because you can call it without first creating an object of the class in which the method is declared.* We discuss static methods in Chapter 6, *Methods: A Deeper Look*.

In this application, we'd like to call class `GradeBook`'s `displayMessage` method to display the welcome message in the command window. Typically, you cannot call a method that belongs to another class until you create an object of that class, as shown in line 10. We begin by declaring variable `myGradeBook`. The variable's type is `GradeBook`—the class we declared in Fig. 3.1. Each new *class* you create becomes a new *type* that can be used to declare variables and create objects. You can declare new class types as needed; this is one reason why Java is known as an **extensible language**.

Variable `myGradeBook` is initialized (line 10) with the result of the **class instance creation expression** `new GradeBook()`. Keyword **new** creates a new object of the class specified to the right of the keyword (i.e., `GradeBook`). The parentheses to the right of `GradeBook` are required. As you'll learn in Section 3.6, those parentheses in combination with a class name represent a call to a **constructor**, which is similar to a method but is used only at the time an object is *created* to *initialize* the object's data. You'll see that data can be placed in the parentheses to specify *initial values* for the object's data. For now, we simply leave the parentheses empty.

Just as we can use object `System.out` to call its methods `print`, `printf` and `println`, we can use object `myGradeBook` to call its method `displayMessage`. Line 13 calls the method `displayMessage` (lines 7–10 of Fig. 3.1) using `myGradeBook` followed by a **dot separator** (`.`), the method name `displayMessage` and an empty set of parentheses. This call causes the `displayMessage` method to perform its task. This method call differs from those in Chapter 2 that displayed information in a command window—each of those method calls provided arguments that specified the data to display. At the beginning of line 13, “`myGradeBook.`” indicates that `main` should use the `myGradeBook` object that was created in line 10. Line 7 of Fig. 3.1 indicates that method `displayMessage` has an *empty parameter list*—that is, `displayMessage` does *not* require additional information to perform its task. For this reason, the method call (line 13 of Fig. 3.2) specifies an empty set of parentheses after the method name to indicate that *no arguments* are being passed to method `displayMessage`. When method `displayMessage` completes its task, method `main` continues executing at line 14. This is the end of method `main`, so the program terminates.

Any class can contain a `main` method. The JVM invokes the `main` method *only* in the class used to execute the application. If an application has multiple classes that contain `main`, the one that’s invoked is the one in the class named in the `java` command.

### Compiling an Application with Multiple Classes

You must compile the classes in Fig. 3.1 and Fig. 3.2 before you can execute the application. First, change to the directory that contains the application’s source-code files. Next, type the command

```
javac GradeBook.java GradeBookTest.java
```

to compile *both* classes at once. If the directory containing the application includes only this application’s files, you can compile *all* the classes in the directory with the command

```
javac *.java
```

The asterisk (`*`) in `*.java` indicates that *all* files in the current directory that end with the file-name extension “`.java`” should be compiled.

### UML Class Diagram for Class `GradeBook`

Figure 3.3 presents a **UML class diagram** for class `GradeBook` of Fig. 3.1. In the UML, each class is modeled in a class diagram as a rectangle with three compartments. The top compartment contains the name of the class centered horizontally in boldface type. The middle compartment contains the class’s attributes, which correspond to instance variables (discussed in Section 3.4) in Java. In Fig. 3.3, the middle compartment is empty, because this `GradeBook` class does *not* have any attributes. The bottom compartment contains the

**Fig. 3.3** | UML class diagram indicating that class `GradeBook` has a public `displayMessage` operation.

class's **operations**, which correspond to methods in Java. The UML models operations by listing the operation name preceded by an access modifier (in this case `+`) and followed by a set of parentheses. Class `GradeBook` has one method, `displayMessage`, so the bottom compartment of Fig. 3.3 lists one operation with this name. Method `displayMessage` does *not* require additional information to perform its tasks, so the parentheses following the method name in the class diagram are *empty*, just as they were in the method's declaration in line 7 of Fig. 3.1. The plus sign (`+`) in front of the operation name indicates that `displayMessage` is a public operation in the UML (i.e., a `public` method in Java). We'll often use UML class diagrams to summarize a class's attributes and operations.

### 3.3 Declaring a Method with a Parameter

In our car analogy from Section 1.6, we discussed the fact that pressing a car's gas pedal sends a *message* to the car to *perform a task*—to go faster. But *how fast* should the car accelerate? As you know, the farther down you press the pedal, the faster the car accelerates. So the message to the car actually includes the *task to perform* and *additional information* that helps the car perform the task. This additional information is known as a **parameter**—the value of the parameter helps the car determine how fast to accelerate. Similarly, a method can require one or more parameters that represent additional information it needs to perform its task. Parameters are defined in a comma-separated **parameter list**, which is located inside the parentheses that follow the method name. Each parameter must specify a *type* and a variable name. The parameter list may contain any number of parameters, including none at all. Empty parentheses following the method name (as in Fig. 3.1, line 7) indicate that a method does *not* require any parameters.

#### *Arguments to a Method*

A method call supplies values—called *arguments*—for each of the method's parameters. For example, the method `System.out.println` requires an argument that specifies the data to output in a command window. Similarly, to make a deposit into a bank account, a `deposit` method specifies a parameter that represents the deposit amount. When the `deposit` method is called, an argument value representing the deposit amount is assigned to the method's parameter. The method then makes a deposit of that amount.

#### *Class Declaration with a Method That Has One Parameter*

We now declare class `GradeBook` (Fig. 3.4) with a `displayMessage` method that displays the course name as part of the welcome message. (See the sample execution in Fig. 3.5.) The new method requires a parameter that represents the course name to output.

Before discussing the new features of class `GradeBook`, let's see how the new class is used from the `main` method of class `GradeBookTest` (Fig. 3.5). Line 12 creates a `Scanner` named `input` for reading the course name from the user. Line 15 creates the `GradeBook` object `myGradeBook`. Line 18 prompts the user to enter a course name. Line 19 reads the name from the user and assigns it to the `nameOfCourse` variable, using `Scanner` method `nextLine` to perform the input. The user types the course name and presses *Enter* to submit the course name to the program. Pressing *Enter* inserts a newline character at the end of the characters typed by the user. Method `nextLine` reads characters typed by the user until it encounters the newline character, then returns a `String` containing the characters up to, but *not* including, the newline. The newline character is *discarded*.

```

2 // Class declaration with one method that has a parameter.
3
4 public class GradeBook
5 {
6     // display a welcome message to the GradeBook user
7     public void displayMessage( String courseName )
8     {
9         System.out.printf( "Welcome to the grade book for\n%s!\n",
10             courseName );
11     } // end method displayMessage
12 } // end class GradeBook

```

**Fig. 3.4** | Class declaration with one method that has a parameter.

```

1 // Fig. 3.5: GradeBookTest.java
2 // Create GradeBook object and pass a String to
3 // its displayMessage method.
4 import java.util.Scanner; // program uses Scanner
5
6 public class GradeBookTest
7 {
8     // main method begins program execution
9     public static void main( String[] args )
10    {
11        // create Scanner to obtain input from command window
12        Scanner input = new Scanner( System.in );
13
14        // create a GradeBook object and assign it to myGradeBook
15        GradeBook myGradeBook = new GradeBook();
16
17        // prompt for and input course name
18        System.out.println( "Please enter the course name:" );
19        String nameOfCourse = input.nextLine(); // read a line of text
20        System.out.println(); // outputs a blank line
21
22        // call myGradeBook's displayMessage method
23        // and pass nameOfCourse as an argument
24        myGradeBook.displayMessage( nameOfCourse );
25    } // end main
26 } // end class GradeBookTest

```

```

Please enter the course name:
CS101 Introduction to Java Programming

Welcome to the grade book for
CS101 Introduction to Java Programming!

```

**Fig. 3.5** | Create a GradeBook object and pass a String to its displayMessage method.

Class Scanner also provides a similar method—**next**—that reads individual words. When the user presses *Enter* after typing input, method next reads characters until it encounters a *white-space character* (such as a space, tab or newline), then returns a String containing

the characters up to, but *not* including, the white-space character (which is discarded). All information after the first white-space character is not lost—it can be read by other statements that call the Scanner’s methods later in the program. Line 20 outputs a blank line.

Line 24 calls `myGradeBooks`’s `displayMessage` method. The variable `nameOfCourse` in parentheses is the *argument* that’s passed to method `displayMessage` so that the method can perform its task. The value of variable `nameOfCourse` in `main` becomes the value of method `displayMessage`’s *parameter* `courseName` in line 7 of Fig. 3.4. When you execute this application, notice that method `displayMessage` outputs the name you type as part of the welcome message (Fig. 3.5).

### More on Arguments and Parameters

In Fig. 3.4, `displayMessage`’s parameter list (line 7) declares one parameter indicating that the method requires a `String` to perform its task. When the method is called, the argument value in the call is assigned to the corresponding parameter (`courseName`) in the method header. Then, the method body uses the value of the `courseName` parameter. Lines 9–10 of Fig. 3.4 display parameter `courseName`’s value, using the `%s` format specifier in `printf`’s format string. The parameter variable’s name (`courseName` in Fig. 3.4, line 7) can be the *same* or *different* from the argument variable’s name (`nameOfCourse` in Fig. 3.5, line 24).

The number of arguments in a method call *must* match the number of parameters in the parameter list of the method’s declaration. Also, the argument types in the method call must be “consistent with” the types of the corresponding parameters in the method’s declaration. (As you’ll learn in Chapter 6, an argument’s type and its corresponding parameter’s type are not always required to be *identical*.) In our example, the method call passes one argument of type `String` (`nameOfCourse` is declared as a `String` in line 19 of Fig. 3.5) and the method declaration specifies one parameter of type `String` (`courseName` is declared as a `String` in line 7 of Fig. 3.4). So in this example the type of the argument in the method call exactly matches the type of the parameter in the method header.

### Updated UML Class Diagram for Class `GradeBook`

The UML class diagram of Fig. 3.6 models class `GradeBook` of Fig. 3.4. Like Fig. 3.1, this `GradeBook` class contains `public` operation `displayMessage`. However, this version of `displayMessage` has a parameter. The UML models a parameter a bit differently from Java by listing the parameter name, followed by a colon and the parameter type in the parentheses following the operation name. The UML has its own data types similar to those of Java (but, as you’ll see, not all the UML data types have the same names as the corresponding Java types). The UML type `String` does correspond to the Java type `String`. `GradeBook` method `displayMessage` (Fig. 3.4) has a `String` parameter named `courseName`, so Fig. 3.6 lists `courseName : String` between the parentheses following `displayMessage`.

**Fig. 3.6** | UML class diagram indicating that class `GradeBook` has a `displayMessage` operation with a `courseName` parameter of UML type `String`.

### Notes on `import` Declarations

Notice the `import` declaration in Fig. 3.5 (line 4). This indicates to the compiler that the program uses class `Scanner`. Why do we need to import class `Scanner`, but not classes `System`, `String` or `GradeBook`? Classes `System` and `String` are in package `java.lang`, which is implicitly imported into *every* Java program, so all programs can use that package's classes *without* explicitly importing them. Most other classes you'll use in Java programs must be imported explicitly.

There's a special relationship between classes that are compiled in the same directory on disk, like classes `GradeBook` and `GradeBookTest`. By default, such classes are considered to be in the same package—known as the **default package**. Classes in the same package are *implicitly imported* into the source-code files of other classes in the same package. Thus, an `import` declaration is *not* required when one class in a package uses another in the same package—such as when class `GradeBookTest` uses class `GradeBook`.

The `import` declaration in line 4 is *not* required if we always refer to class `Scanner` as `java.util.Scanner`, which includes the *full package name and class name*. This is known as the class's **fully qualified class name**. For example, line 12 could be written as

```
java.util.Scanner input = new java.util.Scanner( System.in );
```

### Software Engineering Observation 3.1

*The Java compiler does not require `import` declarations in a Java source-code file if the fully qualified class name is specified every time a class name is used in the source code. Most Java programmers prefer to use `import` declarations.*

## 3.4 Instance Variables, set Methods and get Methods

In Chapter 2, we declared all of an application's variables in the application's `main` method. Variables declared in the body of a particular method are known as **local variables** and can be used only in that method. When that method terminates, the values of its local variables are lost. Recall from Section 1.6 that an object has *attributes* that are carried with it as it's used in a program. Such attributes exist before a method is called on an object, while the method is executing and after the method completes execution.

A class normally consists of one or more methods that manipulate the attributes that belong to a particular object of the class. Attributes are represented as variables in a class declaration. Such variables are called **fields** and are declared *inside* a class declaration but *outside* the bodies of the class's method declarations. When each object of a class maintains its own copy of an attribute, the field that represents the attribute is also known as an **instance variable**—each object (instance) of the class has a separate instance of the variable in memory. The example in this section demonstrates a `GradeBook` class that contains a `courseName` instance variable to represent a particular `GradeBook` object's course name.

### *GradeBook Class with an Instance Variable, a set Method and a get Method*

In our next application (Figs. 3.7–3.8), class `GradeBook` (Fig. 3.7) maintains the course name as an instance variable so that it can be used or modified at any time during an application's execution. The class contains three methods—`setCourseName`, `getCourseName` and `displayMessage`. Method `setCourseName` stores a course name in a `GradeBook`. Method `getCourseName` obtains a `GradeBook`'s course name. Method `displayMessage`,

which now specifies no parameters, still displays a welcome message that includes the course name; as you'll see, the method now obtains the course name by calling a method in the same class—`getCourseName`.

---

```

1 // Fig. 3.7: GradeBook.java
2 // GradeBook class that contains a courseName instance variable
3 // and methods to set and get its value.
4
5 public class GradeBook
6 {
7     private String courseName; // course name for this GradeBook
8
9     // method to set the course name
10    public void setCourseName( String name )
11    {
12        courseName = name; // store the course name
13    } // end method setCourseName
14
15    // method to retrieve the course name
16    public String getCourseName()
17    {
18        return courseName;
19    } // end method getCourseName
20
21    // display a welcome message to the GradeBook user
22    public void displayMessage()
23    {
24        // calls getCourseName to get the name of
25        // the course this GradeBook represents
26        System.out.printf( "Welcome to the grade book for\n%s!\n",
27            getCourseName() );
28    } // end method displayMessage
29 } // end class GradeBook

```

---

**Fig. 3.7** | GradeBook class that contains a `courseName` instance variable and methods to set and get its value.

A typical instructor teaches more than one course, each with its own course name. Line 7 declares `courseName` as a variable of type `String`. Because the variable is declared *in* the body of the class but *outside* the bodies of the class's methods (lines 10–13, 16–19 and 22–28), line 7 is a declaration for an *instance variable*. Every instance (i.e., object) of class `GradeBook` contains one copy of each instance variable. For example, if there are two `GradeBook` objects, each object has its own copy of `courseName`. A benefit of making `courseName` an instance variable is that all the methods of the class (in this case, `GradeBook`) can manipulate any instance variables that appear in the class (in this case, `courseName`).

### *Access Modifiers **public** and **private***

Most instance-variable declarations are preceded with the keyword `private` (as in line 7). Like `public`, keyword **private** is an *access modifier*. *Variables or methods declared with access modifier `private` are accessible only to methods of the class in which they're declared.* Thus,

variable `courseName` can be used only in methods `setCourseName`, `getCourseName` and `displayMessage` of (every object of) class `GradeBook`.

Declaring instance variables with access modifier `private` is known as **data hiding** or information hiding. When a program creates (instantiates) an object of class `GradeBook`, variable `courseName` is *encapsulated* (hidden) in the object and can be accessed only by methods of the object's class. This prevents `courseName` from being modified accidentally by a class in another part of the program. In class `GradeBook`, methods `setCourseName` and `getCourseName` manipulate the instance variable `courseName`.

### Software Engineering Observation 3.2

*Precede each field and method declaration with an access modifier. Generally, instance variables should be declared `private` and methods `public`. (It's appropriate to declare certain methods `private`, if they'll be accessed only by other methods of the class.)*

### Good Programming Practice 3.1

*We prefer to list a class's fields first, so that, as you read the code, you see the names and types of the variables before they're used in the class's methods. You can list the class's fields anywhere in the class outside its method declarations, but scattering them can lead to hard-to-read code.*

### Methods `setCourseName` and `getCourseName`

Method `setCourseName` (lines 10–13) does not return any data when it completes its task, so its return type is `void`. The method receives one parameter—`name`—which represents the course name that will be passed to the method as an argument. Line 12 assigns `name` to instance variable `courseName`.

Method `getCourseName` (lines 16–19) returns a particular `GradeBook` object's `courseName`. The method has an empty parameter list, so it does not require additional information to perform its task. The method specifies that it returns a `String`—this is the method's return type. When a method that specifies a return type other than `void` is called and completes its task, the method returns a *result* to its calling method. For example, when you go to an automated teller machine (ATM) and request your account balance, you expect the ATM to give you back a value that represents your balance. Similarly, when a statement calls method `getCourseName` on a `GradeBook` object, the statement expects to receive the `GradeBook`'s course name (in this case, a `String`, as specified in the method declaration's return type).

The **return** statement in line 18 passes the value of instance variable `courseName` back to the statement that calls method `getCourseName`. Consider, method `displayMessage`'s line 27, which calls method `getCourseName`. When the value is returned, the statement in lines 26–27 uses that value to output the course name. Similarly, if you have a method `square` that returns the square of its argument, you'd expect the statement

```
int result = square( 2 );
```

to return 4 from method `square` and assign 4 to the variable `result`. If you have a method `maximum` that returns the largest of three integer arguments, you'd expect the statement

```
int biggest = maximum( 27, 114, 51 );
```

to return 114 from method `maximum` and assign 114 to variable `biggest`.

The statements in lines 12 and 18 each use `courseName` *even though it was not declared in any of the methods*. We can use `courseName` in `GradeBook`'s methods because `courseName` is an instance variable of the class.

### **Method `displayMessage`**

Method `displayMessage` (lines 22–28) does *not* return any data when it completes its task, so its return type is `void`. The method does *not* receive parameters, so the parameter list is empty. Lines 26–27 output a welcome message that includes the value of instance variable `courseName`, which is returned by the call to method `getCourseName` in line 27. Notice that one method of a class (`displayMessage` in this case) can call another method of the *same* class by using just the method name (`getCourseName` in this case).

### **GradeBookTest Class That Demonstrates Class `GradeBook`**

Class `GradeBookTest` (Fig. 3.8) creates one object of class `GradeBook` and demonstrates its methods. Line 14 creates a `GradeBook` object and assigns it to local variable `myGradeBook` of type `GradeBook`. Lines 17–18 display the initial course name calling the object's `getCourseName` method. The first line of the output shows the name “null.” *Unlike local variables, which are not automatically initialized, every field has a default initial value—a value provided by Java when you do not specify the field's initial value.* Thus, fields are *not* required to be explicitly initialized before they're used in a program—unless they must be initialized to values *other than* their default values. The default value for a field of type `String` (like `courseName` in this example) is `null`, which we say more about in Section 3.5.

Line 21 prompts the user to enter a course name. Local `String` variable `theName` (declared in line 22) is initialized with the course name entered by the user, which is returned by the call to the `nextLine` method of the `Scanner` object `input`. Line 23 calls object `myGradeBook`'s `setCourseName` method and supplies `theName` as the method's argument. When the method is called, the argument's value is assigned to parameter `name` (line 10, Fig. 3.7) of method `setCourseName` (lines 10–13, Fig. 3.7). Then the parameter's value is assigned to instance variable `courseName` (line 12, Fig. 3.7). Line 24 (Fig. 3.8) skips a line in the output, then line 27 calls object `myGradeBook`'s `displayMessage` method to display the welcome message containing the course name.

**Fig. 3.8** | Creating and manipulating a GradeBook object. (Part 2 of 2.)

### *set and get Methods*

A class's private fields can be manipulated *only* by the class's methods. So a **client of an object**—that is, any class that calls the object's methods—calls the class's public methods to manipulate the private fields of an object of the class. This is why the statements in method main (Fig. 3.8) call the `setCourseName`, `getCourseName` and `displayMessage` methods on a `GradeBook` object. Classes often provide public methods to allow clients to *set* (i.e., assign values to) or *get* (i.e., obtain the values of) private instance variables. The names of these methods need not begin with *set* or *get*, but this naming convention is recommended and is convention for special Java software components called JavaBeans, which can simplify programming in many Java integrated development environments (IDEs). The method that *sets* instance variable `courseName` in this example is called `setCourseName`, and the method that *gets* its value is called `getCourseName`.

### *GradeBook UML Class Diagram with an Instance Variable and set and get Methods*

Figure 3.9 contains an updated UML class diagram for the version of class `GradeBook` in Fig. 3.7. This diagram models class `GradeBook`'s instance variable `courseName` as an attribute in the middle compartment of the class. The UML represents instance variables as attributes by listing the attribute name, followed by a colon and the attribute type. The UML type of attribute `courseName` is `String`. Instance variable `courseName` is private in Java, so the class diagram lists a minus sign (-) access modifier in front of the corresponding attribute's name. Class `GradeBook` contains three public methods, so the class diagram lists three operations in the third compartment. Recall that the plus sign (+) before each operation name indicates that the operation is public. Operation `setCourseName` has a `String` parameter called `name`. The UML indicates the return type of an operation by placing a colon and the return type after the parentheses following the operation name. Method `getCourseName` of class `GradeBook` (Fig. 3.7) has a `String` return type in Java, so the

class diagram shows a `String` return type in the UML. Operations `setCourseName` and `displayMessage` *do not* return values (i.e., they return `void` in Java), so the UML class diagram *does not* specify a return type after the parentheses of these operations.

**Fig. 3.9** | UML class diagram indicating that class `GradeBook` has a private `courseName` attribute of UML type `String` and three public operations—`setCourseName` (with a name parameter of UML type `String`), `getCourseName` (which returns UML type `String`) and `displayMessage`.

### 3.5 Primitive Types vs. Reference Types

Java’s types are divided into primitive types and **reference types**. The primitive types are `boolean`, `byte`, `char`, `short`, `int`, `long`, `float` and `double`. All nonprimitive types are reference types, so classes, which specify the types of objects, are reference types.

A primitive-type variable can store exactly one *value of its declared type* at a time. For example, an `int` variable can store one whole number (such as 7) at a time. When another value is assigned to that variable, its initial value is replaced. Primitive-type instance variables are *initialized by default*—variables of types `byte`, `char`, `short`, `int`, `long`, `float` and `double` are initialized to 0, and variables of type `boolean` are initialized to `false`. You can specify your own initial value for a primitive-type variable by assigning the variable a value in its declaration, as in

```
private int numberOfStudents = 10;
```

Recall that local variables are *not* initialized by default.

#### Error-Prevention Tip 3.1

*An attempt to use an uninitialized local variable causes a compilation error.*

Programs use variables of reference types (normally called **references**) to store the *locations* of objects in the computer’s memory. Such a variable is said to **refer to an object** in the program. Objects that are referenced may each contain many instance variables. Line 14 of Fig. 3.8 creates an object of class `GradeBook`, and the variable `myGradeBook` contains a reference to that `GradeBook` object. *Reference-type instance variables are initialized by default to the value `null`*—a reserved word that represents a “reference to nothing.” This is why the first call to `getCourseName` in line 18 of Fig. 3.8 returned `null`—the value of `courseName` had not been set, so the default initial value `null` was returned. The complete list of reserved words and keywords is listed in Appendix C.

When you use an object of another class, a reference to the object is required to **invoke** (i.e., call) its methods. In the application of Fig. 3.8, the statements in method `main` use

the variable `myGradeBook` to send messages to the `GradeBook` object. These messages are calls to methods (like `setCourseName` and `getCourseName`) that enable the program to interact with the `GradeBook` object. For example, the statement in line 23 uses `myGradeBook` to send the `setCourseName` message to the `GradeBook` object. The message includes the argument that `setCourseName` requires to perform its task. The `GradeBook` object uses this information to set the `courseName` instance variable. Primitive-type variables do not refer to objects, so such variables cannot be used to invoke methods.

### Software Engineering Observation 3.3

A variable's declared type (e.g., `int`, `double` or `GradeBook`) indicates whether the variable is of a primitive or a reference type. If a variable is not of one of the eight primitive types, then it's of a reference type.

## 3.6 Initializing Objects with Constructors

As mentioned in Section 3.4, when an object of class `GradeBook` (Fig. 3.7) is created, its instance variable `courseName` is initialized to `null` by default. What if you want to provide a course name when you create a `GradeBook` object? Each class you declare can provide a special method called a constructor that can be used to initialize an object of a class when the object is created. In fact, Java *requires* a constructor call for *every* object that's created. Keyword `new` requests memory from the system to store an object, then calls the corresponding class's constructor to initialize the object. The call is indicated by the parentheses after the class name. A constructor *must* have the *same name* as the class. For example, line 14 of Fig. 3.8 first uses `new` to create a `GradeBook` object. The empty parentheses after “`new GradeBook`” indicate a call to the class's constructor without arguments. By default, the compiler provides a **default constructor** with *no parameters* in any class that does *not* explicitly include a constructor. When a class has only the default constructor, its instance variables are initialized to their *default values*.

When you declare a class, you can provide your own constructor to specify custom initialization for objects of your class. For example, you might want to specify a course name for a `GradeBook` object when the object is created, as in

```
GradeBook myGradeBook =
    new GradeBook( "CS101 Introduction to Java Programming" );
```

In this case, the argument “`CS101 Introduction to Java Programming`” is passed to the `GradeBook` object's constructor and used to initialize the `courseName`. The preceding statement requires that the class provide a constructor with a `String` parameter. Figure 3.10 contains a modified `GradeBook` class with such a constructor.

```
1 // Fig. 3.10: GradeBook.java
2 // GradeBook class with a constructor to initialize the course name.
3
4 public class GradeBook
5 {
6     private String courseName; // course name for this GradeBook
7 }
```

**Fig. 3.10** | `GradeBook` class with a constructor to initialize the course name. (Part I of 2.)

```

8 // constructor initializes courseName with String argument
9 public GradeBook( String name ) // constructor name is class name
10 {
11     courseName = name; // initializes courseName
12 } // end constructor
13
14 // method to set the course name
15 public void setCourseName( String name )
16 {
17     courseName = name; // store the course name
18 } // end method setCourseName
19
20 // method to retrieve the course name
21 public String getCourseName()
22 {
23     return courseName;
24 } // end method getCourseName
25
26 // display a welcome message to the GradeBook user
27 public void displayMessage()
28 {
29     // this statement calls getCourseName to get the
30     // name of the course this GradeBook represents
31     System.out.printf( "Welcome to the grade book for\n%s!\n",
32         getCourseName() );
33 } // end method displayMessage
34 } // end class GradeBook

```

**Fig. 3.10** | GradeBook class with a constructor to initialize the course name. (Part 2 of 2.)

Lines 9–12 declare GradeBook’s constructor. Like a method, a constructor’s parameter list specifies the data it requires to perform its task. When you create a new object (as we’ll do in Fig. 3.11), this data is placed in the *parentheses that follow the class name*. Line 9 of Fig. 3.10 indicates that the constructor has a String parameter called name. The name passed to the constructor is assigned to instance variable courseName in line 11.

Figure 3.11 initializes GradeBook objects using the constructor. Lines 11–12 create and initialize the GradeBook object gradeBook1. The GradeBook constructor is called with the argument "CS101 Introduction to Java Programming" to initialize the course name. The class instance creation expression in lines 11–12 returns a reference to the new object, which is assigned to the variable gradeBook1. Lines 13–14 repeat this process, this time passing the argument "CS102 Data Structures in Java" to initialize the course name for gradeBook2. Lines 17–20 use each object’s getCourseName method to obtain the course names and show that they were initialized when the objects were created. The output confirms that each GradeBook maintains its own copy of instance variable courseName.

An important difference between constructors and methods is that constructors cannot return values, so they cannot specify a return type (not even void). Normally, constructors are declared public. If a class does not include a constructor, the class’s instance variables are initialized to their default values. *If you declare any constructors for a class, the Java compiler will not create a default constructor for that class.* Thus, we can no longer create a GradeBook object with new GradeBook() as we did in the earlier examples.

```

1 // Fig. 3.11: GradeBookTest.java
2 // GradeBook constructor used to specify the course name at the
3 // time each GradeBook object is created.
4
5 public class GradeBookTest
6 {
7     // main method begins program execution
8     public static void main( String[] args )
9     {
10        // create GradeBook object
11        GradeBook gradeBook1 = new GradeBook(
12            "CS101 Introduction to Java Programming" );
13        GradeBook gradeBook2 = new GradeBook(
14            "CS102 Data Structures in Java" );
15
16        // display initial value of courseName for each GradeBook
17        System.out.printf( "gradeBook1 course name is: %s\n",
18            gradeBook1.getCourseName() );
19        System.out.printf( "gradeBook2 course name is: %s\n",
20            gradeBook2.getCourseName() );
21    } // end main
22 } // end class GradeBookTest

```

```

gradeBook1 course name is: CS101 Introduction to Java Programming
gradeBook2 course name is: CS102 Data Structures in Java

```

**Fig. 3.11** | GradeBook constructor used to specify the course name at the time each GradeBook object is created.

### Software Engineering Observation 3.4

*Unless default initialization of your class's instance variables is acceptable, provide a constructor to ensure that they're properly initialized with meaningful values when each new object of your class is created.*

### Adding the Constructor to Class *GradeBook*'s UML Class Diagram

The UML class diagram of Fig. 3.12 models class *GradeBook* of Fig. 3.10, which has a constructor that has a name parameter of type *String*. Like operations, the UML models constructors in the third compartment of a class in a class diagram. To distinguish a

**Fig. 3.12** | UML class diagram indicating that class *GradeBook* has a constructor that has a name parameter of UML type *String*.

constructor from a class’s operations, the UML requires that the word “constructor” be placed between **guillemets** (« and ») before the constructor’s name. It’s *customary* to list constructors *before* other operations in the third compartment.

### Constructors with Multiple Parameters

Sometimes you’ll want to initialize objects with multiple data items. In Exercise 3.11, we ask you to store the course name *and* the instructor’s name in a GradeBook object. In this case, the GradeBook’s constructor would be modified to receive two Strings, as in

```
public GradeBook( String courseName, String instructorName )
```

and you’d call the GradeBook constructor as follows:

```
GradeBook gradeBook = new GradeBook(
    "CS101 Introduction to Java Programming", "Sue Green" );
```

## 3.7 Floating-Point Numbers and Type double

We now depart temporarily from our GradeBook case study to declare an Account class that maintains the balance of a bank account. Most account balances are not whole numbers (such as 0, −22 and 1024). For this reason, class Account represents the account balance as a **floating-point number** (i.e., a number with a decimal point, such as 7.33, 0.0975 or 1000.12345). Java provides two primitive types for storing floating-point numbers in memory—float and double. They differ primarily in that double variables can store numbers with larger magnitude and finer detail (i.e., more digits to the right of the decimal point—also known as the number’s **precision**) than float variables.

### Floating-Point Number Precision and Memory Requirements

Variables of type **float** represent **single-precision floating-point numbers** and can represent up to *seven significant digits*. Variables of type **double** represent **double-precision floating-point numbers**. These require twice as much memory as float variables and provide *15 significant digits*—approximately double the precision of float variables. For the range of values required by most programs, variables of type float should suffice, but you can use double to “play it safe.” In some applications, even double variables will be inadequate. Most programmers represent floating-point numbers with type double. In fact, Java treats all floating-point numbers you type in a program’s source code (such as 7.33 and 0.0975) as double values by default. Such values in the source code are known as **floating-point literals**. See Appendix D, Primitive Types, for the ranges of values for floats and doubles.

Although floating-point numbers are not always 100% precise, they have numerous applications. For example, when we speak of a “normal” body temperature of 98.6, we do not need to be precise to a large number of digits. When we read the temperature on a thermometer as 98.6, it may actually be 98.5999473210643. Calling this number simply 98.6 is fine for most applications involving body temperatures. Owing to the imprecise nature of floating-point numbers, type double is preferred over type float, because double variables can represent floating-point numbers more accurately. For this reason, we primarily use type double throughout the book. For precise floating-point numbers, Java provides class `BigDecimal` (package `java.math`).

Floating-point numbers also arise as a result of division. In conventional arithmetic, when we divide 10 by 3, the result is 3.3333333..., with the sequence of 3s repeating infi-

nity. The computer allocates only a fixed amount of space to hold such a value, so clearly the stored floating-point value can be only an approximation.

### *Account Class with an Instance Variable of Type `double`*

Our next application (Figs. 3.13–3.14) contains a class named `Account` (Fig. 3.13) that maintains the balance of a bank account. A typical bank services many accounts, each with its own balance, so line 7 declares an instance variable named `balance` of type `double`. It’s an instance variable because it’s declared in the body of the class but outside the class’s method declarations (lines 10–16, 19–22 and 25–28). Every instance (i.e., object) of class `Account` contains its own copy of `balance`.

---

```

1 // Fig. 3.13: Account.java
2 // Account class with a constructor to validate and
3 // initialize instance variable balance of type double.
4
5 public class Account
6 {
7     private double balance; // instance variable that stores the balance
8
9     // constructor
10    public Account( double initialBalance )
11    {
12        // validate that initialBalance is greater than 0.0;
13        // if it is not, balance is initialized to the default value 0.0
14        if ( initialBalance > 0.0 )
15            balance = initialBalance;
16    } // end Account constructor
17
18    // credit (add) an amount to the account
19    public void credit( double amount )
20    {
21        balance = balance + amount; // add amount to balance
22    } // end method credit
23
24    // return the account balance
25    public double getBalance()
26    {
27        return balance; // gives the value of balance to the calling method
28    } // end method getBalance
29 } // end class Account

```

---

**Fig. 3.13** | `Account` class with a constructor to validate and initialize instance variable `balance` of type `double`.

The class has a constructor and two methods. It’s common for someone opening an account to deposit money immediately, so the constructor (lines 10–16) receives a parameter `initialBalance` of type `double` that represents the *starting balance*. Lines 14–15 ensure that `initialBalance` is greater than 0.0. If so, `initialBalance`’s value is assigned to instance variable `balance`. Otherwise, `balance` remains at 0.0—its default initial value.

Method `credit` (lines 19–22) does *not* return any data when it completes its task, so its return type is `void`. The method receives one parameter named `amount`—a `double`

value that will be added to the balance. Line 21 adds amount to the current value of balance, then assigns the result to balance (thus replacing the prior balance amount).

Method getBalance (lines 25–28) allows clients of the class (i.e., other classes that use this class) to obtain the value of a particular Account object's balance. The method specifies return type double and an empty parameter list.

Once again, the statements in lines 15, 21 and 27 use instance variable balance even though it was *not* declared in any of the methods. We can use balance in these methods because it's an instance variable of the class.

### AccountTest Class to Use Class Account

Class AccountTest (Fig. 3.14) creates two Account objects (lines 10–11) and initializes them with 50.00 and -7.53, respectively. Lines 14–17 output the balance in each Account by calling the Account's getBalance method. When method getBalance is called for account1 from line 15, the value of account1's balance is returned from line 27 of Fig. 3.13 and displayed by the System.out.printf statement (Fig. 3.14, lines 14–15). Similarly, when method getBalance is called for account2 from line 17, the value of the account2's balance is returned from line 27 of Fig. 3.13 and displayed by the System.out.printf statement (Fig. 3.14, lines 16–17). The balance of account2 is 0.00, because the constructor ensured that the account could *not* begin with a negative balance. The value is output by printf with the format specifier %.2f. The format specifier %f is used to output values of type float or double. The .2 between % and f represents the number of decimal places (2) that should be output to the right of the decimal point in the floating-point number—also known as the number's **precision**. Any floating-point value output with %.2f will be rounded to the hundredths position—for example, 123.457 would be rounded to 123.46, 27.333 would be rounded to 27.33 and 123.455 would be rounded to 123.46.

---

```

1 // Fig. 3.14: AccountTest.java
2 // Inputting and outputting floating-point numbers with Account objects.
3 import java.util.Scanner;
4
5 public class AccountTest
6 {
7     // main method begins execution of Java application
8     public static void main( String[] args )
9     {
10         Account account1 = new Account( 50.00 ); // create Account object
11         Account account2 = new Account( -7.53 ); // create Account object
12
13         // display initial balance of each object
14         System.out.printf( "account1 balance: %.2f\n",
15             account1.getBalance() );
16         System.out.printf( "account2 balance: %.2f\n\n",
17             account2.getBalance() );
18
19         // create Scanner to obtain input from command window
20         Scanner input = new Scanner( System.in );
21         double depositAmount; // deposit amount read from user

```

---

**Fig. 3.14** | Inputting and outputting floating-point numbers with Account objects. (Part 1 of 2.)

```

22
23     System.out.print( "Enter deposit amount for account1: " ); // prompt
24     depositAmount = input.nextDouble(); // obtain user input
25     System.out.printf( "\nadding %.2f to account1 balance\n\n",
26         depositAmount );
27     account1.credit( depositAmount ); // add to account1 balance
28
29     // display balances
30     System.out.printf( "account1 balance: $%.2f\n",
31         account1.getBalance() );
32     System.out.printf( "account2 balance: $%.2f\n\n",
33         account2.getBalance() );
34
35     System.out.print( "Enter deposit amount for account2: " ); // prompt
36     depositAmount = input.nextDouble(); // obtain user input
37     System.out.printf( "\nadding %.2f to account2 balance\n\n",
38         depositAmount );
39     account2.credit( depositAmount ); // add to account2 balance
40
41     // display balances
42     System.out.printf( "account1 balance: $%.2f\n",
43         account1.getBalance() );
44     System.out.printf( "account2 balance: $%.2f\n",
45         account2.getBalance() );
46 } // end main
47 } // end class AccountTest

```

```

account1 balance: $50.00
account2 balance: $0.00

Enter deposit amount for account1: 25.53

adding 25.53 to account1 balance

account1 balance: $75.53
account2 balance: $0.00

Enter deposit amount for account2: 123.45

adding 123.45 to account2 balance

account1 balance: $75.53
account2 balance: $123.45

```

**Fig. 3.14** | Inputting and outputting floating-point numbers with Account objects. (Part 2 of 2.)

Line 21 declares local variable `depositAmount` to store each deposit amount entered by the user. Unlike the instance variable `balance` in class `Account`, local variable `depositAmount` in `main` is *not* initialized to 0.0 by default. However, this variable does not need to be initialized here, because its value will be determined by the user's input.

Line 23 prompts the user to enter a deposit amount for account1. Line 24 obtains the input from the user by calling Scanner object `input`'s `nextDouble` method, which returns a `double` value entered by the user. Lines 25–26 display the deposit amount. Line 27 calls

object `account1`'s `credit` method and supplies `depositAmount` as the method's argument. When the method is called, the argument's value is assigned to parameter `amount` (line 19 of Fig. 3.13) of method `credit` (lines 19–22 of Fig. 3.13); then method `credit` adds that value to the `balance` (line 21 of Fig. 3.13). Lines 30–33 (Fig. 3.14) output the balances of both `Accounts` again to show that only `account1`'s balance changed.

Line 35 prompts the user to enter a deposit amount for `account2`. Line 36 obtains the input from the user by calling `Scanner` object `input`'s `nextDouble` method. Lines 37–38 display the deposit amount. Line 39 calls object `account2`'s `credit` method and supplies `depositAmount` as the method's argument; then method `credit` adds that value to the `balance`. Finally, lines 42–45 output the balances of both `Accounts` again to show that only `account2`'s balance changed.

### UML Class Diagram for Class `Account`

The UML class diagram in Fig. 3.15 models class `Account` of Fig. 3.13. The diagram models the private attribute `balance` with UML type `Double` to correspond to the class's instance variable `balance` of Java type `double`. The diagram models class `Account`'s constructor with a parameter `initialBalance` of UML type `Double` in the third compartment of the class. The class's two public methods are modeled as operations in the third compartment as well. The diagram models operation `credit` with an `amount` parameter of UML type `Double` (because the corresponding method has an `amount` parameter of Java type `double`), and operation `getBalance` with a return type of `Double` (because the corresponding Java method returns a `double` value).

**Fig. 3.15** | UML class diagram indicating that class `Account` has a private `balance` attribute of UML type `Double`, a constructor (with a parameter of UML type `Double`) and two public operations—`credit` (with an `amount` parameter of UML type `Double`) and `getBalance` (returns UML type `Double`).

## 3.8 (Optional) GUI and Graphics Case Study: Using Dialog Boxes

This optional case study is designed for those who want to begin learning Java's powerful capabilities for creating graphical user interfaces (GUIs) and graphics early in the book, before the main discussions of these topics in Chapter 14, GUI Components: Part 1, Chapter 15, Graphics and Java 2D, and Chapter 25, GUI Components: Part 2.

The GUI and Graphics Case Study appears in 10 brief sections (see Fig. 3.16). Each section introduces new concepts and provides examples with screen captures that show sample interactions and results. In the first few sections, you'll create your first graphical applications. In subsequent sections, you'll use object-oriented programming concepts to

create an application that draws a variety of shapes. When we formally introduce GUIs in Chapter 14, we use the mouse to choose exactly which shapes to draw and where to draw them. In Chapter 15, we add capabilities of the Java 2D graphics API to draw the shapes with different line thicknesses and fills. We hope you find this case study informative and entertaining.

Location	Title—Exercise(s)
Section 3.8	Using Dialog Boxes—Basic input and output with dialog boxes
Section 4.14	Creating Simple Drawings—Displaying and drawing lines on the screen
Section 5.10	Drawing Rectangles and Ovals—Using shapes to represent data
Section 6.13	Colors and Filled Shapes—Drawing a bull’s-eye and random graphics
Section 7.15	Drawing Arcs—Drawing spirals with arcs
Section 8.16	Using Objects with Graphics—Storing shapes as objects
Section 9.8	Displaying Text and Images Using Labels—Providing status information
Section 10.8	Drawing with Polymorphism—Identifying the similarities between shapes
Exercise 14.17	Expanding the Interface—Using GUI components and event handling
Exercise 15.31	Adding Java 2D—Using the Java 2D API to enhance drawings

**Fig. 3.16** | Summary of the GUI and Graphics Case Study in each chapter.

### *Displaying Text in a Dialog Box*

The programs presented thus far display output in the command window. Many applications use windows or **dialog boxes** (also called **dialogs**) to display output. Web browsers such as Firefox, Internet Explorer, Chrome and Safari display web pages in their own windows. E-mail programs allow you to type and read messages in a window. Typically, dialog boxes are windows in which programs display important messages to users. Class **JOptionPane** provides prebuilt dialog boxes that enable programs to display windows containing messages—such windows are called **message dialogs**. Figure 3.17 displays the String "Welcome\n\t\nJava" in a message dialog.

```

1 // Fig. 3.17: Dialog1.java
2 // Using JOptionPane to display multiple lines in a dialog box.
3 import javax.swing.JOptionPane; // import class JOptionPane
4
5 public class Dialog1
6 {
7     public static void main( String[] args )
8     {
9         // display a dialog with a message
10        JOptionPane.showMessageDialog( null, "Welcome\n\t\nJava" );
11    } // end main
12 } // end class Dialog1

```

**Fig. 3.17** | Using JOptionPane to display multiple lines in a dialog box. (Part 1 of 2.)

**Fig. 3.17** | Using `JOptionPane` to display multiple lines in a dialog box. (Part 2 of 2.)

Line 3 indicates that the program uses class `JOptionPane` from package `javax.swing`. This package contains many classes that help you create **graphical user interfaces (GUIs)**. **GUI components** facilitate data entry by a program’s user and presentation of outputs to the user. Line 10 calls `JOptionPane` method `showMessageDialog` to display a dialog box containing a message. The method requires two arguments. The first helps the Java application determine where to position the dialog box. A dialog is typically displayed from a GUI application with its own window. The first argument refers to that window (known as the parent window) and causes the dialog to appear centered over the application’s window. If the first argument is `null`, the dialog box is displayed at the center of your screen. The second argument is the `String` to display in the dialog box.

### Introducing static Methods

`JOptionPane` method `showMessageDialog` is a so-called **static method**. Such methods often define frequently used tasks. For example, many programs display dialog boxes, and the code to do this is the same each time. Rather than requiring you to “reinvent the wheel” and create code to display a dialog, the designers of class `JOptionPane` declared a static method that performs this task for you. A static method is called by using its class name followed by a dot (`.`) and the method name, as in

```
ClassName.methodName( arguments )
```

Notice that you do *not* create an object of class `JOptionPane` to use its static method `showMessageDialog`. We discuss static methods in more detail in Chapter 6.

### Entering Text in a Dialog

Figure 3.18 uses another predefined `JOptionPane` dialog called an **input dialog** that allows the user to enter data into a program. The program asks for the user’s name and responds with a message dialog containing a greeting and the name that the user entered.

Lines 10–11 use `JOptionPane` method `showInputDialog` to display an input dialog containing a prompt and a field (known as a **text field**) in which the user can enter text. Method `showInputDialog`’s argument is the prompt that indicates what the user should enter. The user types characters in the text field, then clicks the **OK** button or presses the *Enter* key to return the `String` to the program. Method `showInputDialog` (line 11) returns a `String` containing the characters typed by the user. We store the `String` in variable name (line 10). [Note: If you press the dialog’s **Cancel** button or press the *Esc* key, the method returns `null` and the program displays the word “null” as the name.]

Lines 14–15 use static `String` method `format` to return a `String` containing a greeting with the user’s name. Method `format` works like method `System.out.printf`, except that `format` returns the formatted `String` rather than displaying it in a command window. Line 18 displays the greeting in a message dialog, just as we did in Fig. 3.17.

```

1 // Fig. 3.18: NameDialog.java
2 // Basic input with a dialog box.
3 import javax.swing.JOptionPane;
4
5 public class NameDialog
6 {
7     public static void main( String[] args )
8     {
9         // prompt user to enter name
10        String name =
11            JOptionPane.showInputDialog( "What is your name?" );
12
13        // create the message
14        String message =
15            String.format( "Welcome, %s, to Java Programming!", name );
16
17        // display the message to welcome the user by name
18        JOptionPane.showMessageDialog( null, message );
19    } // end main
20 } // end class NameDialog

```

**Fig. 3.18** | Obtaining user input from a dialog.

### GUI and Graphics Case Study Exercise

**3.1** Modify the addition program in Fig. 2.7 to use dialog-based input and output with the methods of class `JOptionPane`. Since method `showInputDialog` returns a `String`, you must convert the `String` the user enters to an `int` for use in calculations. The `Integer` class's static method `parseInt` takes a `String` argument representing an integer (e.g., the result of `JOptionPane.showInputDialog`) and returns the value as an `int`. Method `parseInt` is a static method of class `Integer` (from package `java.lang`). If the `String` does not contain a valid integer, the program will terminate with an error.

## 3.9 Wrap-Up

In this chapter, you learned how to declare instance variables of a class to maintain data for each object of the class, and how to declare methods that operate on that data. You learned how to call a method to tell it to perform its task and how to pass information to methods as arguments. You learned the difference between a local variable of a method and an instance variable of a class and that only instance variables are initialized automatically. You also learned how to use a class's constructor to specify the initial values for an object's instance variables. Throughout the chapter, you saw how the UML can be used to create class diagrams that model the constructors, methods and attributes of classes. Finally, you learned about floating-point numbers—how to store them with variables of primitive type `double`,

how to input them with a Scanner object and how to format them with `printf` and format specifier `%f` for display purposes. In the next chapter we begin our introduction to control statements, which specify the order in which a program's actions are performed. You'll use these in your methods to specify how they should perform their tasks.

## Summary

### *Section 3.2 Declaring a Class with a Method and Instantiating an Object of a Class*

- Each class declaration that begins with the access modifier (p. 72) `public` must be stored in a file that has exactly the same name as the class and ends with the `.java` file-name extension.
- Every class declaration contains keyword `class` followed immediately by the class's name.
- A method declaration that begins with keyword `public` indicates that the method can be called by other classes declared outside the class declaration.
- Keyword `void` indicates that a method will perform a task but will not return any information.
- By convention, method names begin with a lowercase first letter and all subsequent words in the name begin with a capital first letter.
- Empty parentheses following a method name indicate that the method does not require any parameters to perform its task.
- Every method's body is delimited by left and right braces (`{` and `}`).
- The method's body contains statements that perform the method's task. After the statements execute, the method has completed its task.
- When you attempt to execute a class, Java looks for the class's `main` method to begin execution.
- Typically, you cannot call a method of another class until you create an object of that class.
- A class instance creation expression (p. 74) begins with keyword `new` and creates a new object.
- To call a method of an object, follow the variable name with a dot separator (`.`; p. 75), the method name and a set of parentheses containing the method's arguments.
- In the UML, each class is modeled in a class diagram as a rectangle with three compartments. The top compartment contains the class's name centered horizontally in boldface. The middle one contains the class's attributes, which correspond to fields (p. 79) in Java. The bottom one contains the class's operations (p. 76), which correspond to methods and constructors in Java.
- The UML models operations by listing the operation name followed by a set of parentheses. A plus sign (+) in front of the operation name indicates that the operation is a `public` one in the UML (i.e., a `public` method in Java).

### *Section 3.3 Declaring a Method with a Parameter*

- Methods often require parameters (p. 76) to perform their tasks. Such additional information is provided to methods via arguments in method calls.
- Scanner method `nextLine` (p. 76) reads characters until a newline character is encountered, then returns the characters as a `String`.
- Scanner method `next` (p. 77) reads characters until any white-space character is encountered, then returns the characters as a `String`.
- A method that requires data to perform its task must specify this in its declaration by placing additional information in the method's parameter list (p. 76).
- Each parameter must specify both a type and a variable name.

- At the time a method is called, its arguments are assigned to its parameters. Then the method body uses the parameter variables to access the argument values.
- A method specifies multiple parameters in a comma-separated list.
- The number of arguments in the method call must match the number of parameters in the method declaration's parameter list. Also, the argument types in the method call must be consistent with the types of the corresponding parameters in the method's declaration.
- Class `String` is in package `java.lang`, which is imported implicitly into all source-code files.
- By default, classes compiled into the same directory are in the same package. Classes in the same package are implicitly imported into the source-code files of other classes in the same package.
- `import` declarations are not required if you always use fully qualified class names (p. 79).
- The UML models a parameter of an operation by listing the parameter name, followed by a colon and the parameter type between the parentheses following the operation name.
- The UML has its own data types similar to those of Java. Not all the UML data types have the same names as the corresponding Java types.
- The UML type `String` corresponds to the Java type `String`.

### Section 3.4 Instance Variables, set Methods and get Methods

- Variables declared in a method's body are local variables and can be used only in that method.
- A class normally consists of one or more methods that manipulate the attributes (data) that belong to a particular object of the class. Such variables are called fields and are declared inside a class declaration but outside the bodies of the class's method declarations.
- When each object of a class maintains its own copy of an attribute, the corresponding field is known as an instance variable.
- Variables or methods declared with access modifier `private` are accessible only to methods of the class in which they're declared.
- Declaring instance variables with access modifier `private` (p. 80) is known as data hiding.
- A benefit of fields is that all the methods of the class can use the fields. Another distinction between a field and a local variable is that a field has a default initial value (p. 82) provided by Java when you do not specify the field's initial value, but a local variable does not.
- The default value for a field of type `String` (or any other reference type) is `null`.
- When a method that specifies a return type (p. 73) is called and completes its task, the method returns a result to its calling method (p. 73).
- Classes often provide `public` methods to allow the class's clients to *set* or *get* `private` instance variables (p. 83). The names of these methods need not begin with *set* or *get*, but this naming convention is recommended and is required for special Java software components called JavaBeans.
- The UML represents instance variables as an attribute name, followed by a colon and the type.
- Private attributes are preceded by a minus sign (-) in the UML.
- The UML indicates an operation's return type by placing a colon and the return type after the parentheses following the operation name.
- UML class diagrams (p. 75) do not specify return types for operations that do not return values.

### Section 3.5 Primitive Types vs. Reference Types

- Types in Java are divided into two categories—primitive types and reference types. The primitive types are `boolean`, `byte`, `char`, `short`, `int`, `long`, `float` and `double`. All other types are reference types, so classes, which specify the types of objects, are reference types.

- A primitive-type variable can store exactly one value of its declared type at a time.
- Primitive-type instance variables are initialized by default. Variables of types `byte`, `char`, `short`, `int`, `long`, `float` and `double` are initialized to 0. Variables of type `boolean` are initialized to `false`.
- Reference-type variables (called references; p. 84) store the location of an object in the computer's memory. Such variables refer to objects in the program. The object that's referenced may contain many instance variables and methods.
- Reference-type fields are initialized by default to the value `null`.
- A reference to an object (p. 84) is required to invoke an object's instance methods. A primitive-type variable does not refer to an object and therefore cannot be used to invoke a method.

### Section 3.6 Initializing Objects with Constructors

- Keyword `new` requests memory from the system to store an object, then calls the corresponding class's constructor (p. 74) to initialize the object.
- A constructor can be used to initialize an object of a class when the object is created.
- Constructors can specify parameters but cannot specify return types.
- If a class does not define constructors, the compiler provides a default constructor (p. 85) with no parameters, and the class's instance variables are initialized to their default values.
- The UML models constructors in the third compartment of a class diagram. To distinguish a constructor from a class's operations, the UML places the word "constructor" between guillemets (« and »; p. 88) before the constructor's name.

### Section 3.7 Floating-Point Numbers and Type `double`

- A floating-point number (p. 88) is a number with a decimal point. Java provides two primitive types for storing floating-point numbers (p. 88) in memory—`float` and `double`. The primary difference between these types is that `double` variables can store numbers with larger magnitude and finer detail (known as the number's precision; p. 88) than `float` variables.
- Variables of type `float` represent single-precision floating-point numbers and have seven significant digits. Variables of type `double` represent double-precision floating-point numbers. These require twice as much memory as `float` variables and provide 15 significant digits—approximately double the precision of `float` variables.
- Floating-point literals (p. 88) are of type `double` by default.
- Scanner method `nextDouble` (p. 91) returns a `double` value.
- The format specifier `%f` (p. 90) is used to output values of type `float` or `double`. The format specifier `%.2f` specifies that two digits of precision (p. 90) should be output to the right of the decimal point in the floating-point number.
- The default value for a field of type `double` is 0.0, and the default value for a field of type `int` is 0.

## Self-Review Exercises

- 3.1** Fill in the blanks in each of the following:
- Each class declaration that begins with keyword \_\_\_\_\_ must be stored in a file that has exactly the same name as the class and ends with the `.java` file-name extension.
  - Keyword \_\_\_\_\_ in a class declaration is followed immediately by the class's name.
  - Keyword \_\_\_\_\_ requests memory from the system to store an object, then calls the corresponding class's constructor to initialize the object.
  - Each parameter must specify both a(n) \_\_\_\_\_ and a(n) \_\_\_\_\_.
  - By default, classes that are compiled in the same directory are considered to be in the same package, known as the \_\_\_\_\_.

- f) When each object of a class maintains its own copy of an attribute, the field that represents the attribute is also known as a(n) \_\_\_\_\_.
- g) Java provides two primitive types for storing floating-point numbers in memory: \_\_\_\_\_ and \_\_\_\_\_.
- h) Variables of type `double` represent \_\_\_\_\_ floating-point numbers.
- i) Scanner method \_\_\_\_\_ returns a `double` value.
- j) Keyword `public` is an access \_\_\_\_\_.
- k) Return type \_\_\_\_\_ indicates that a method will not return a value.
- l) Scanner method \_\_\_\_\_ reads characters until it encounters a newline character, then returns those characters as a `String`.
- m) Class `String` is in package \_\_\_\_\_.
- n) A(n) \_\_\_\_\_ is not required if you always refer to a class with its fully qualified class name.
- o) A(n) \_\_\_\_\_ is a number with a decimal point, such as 7.33, 0.0975 or 1000.12345.
- p) Variables of type `float` represent \_\_\_\_\_ floating-point numbers.
- q) The format specifier \_\_\_\_\_ is used to output values of type `float` or `double`.
- r) Types in Java are divided into two categories—\_\_\_\_\_ types and \_\_\_\_\_ types.

**3.2** State whether each of the following is *true* or *false*. If *false*, explain why.

- a) By convention, method names begin with an uppercase first letter, and all subsequent words in the name begin with a capital first letter.
- b) An `import` declaration is not required when one class in a package uses another in the same package.
- c) Empty parentheses following a method name in a method declaration indicate that the method does not require any parameters to perform its task.
- d) Variables or methods declared with access modifier `private` are accessible only to methods of the class in which they're declared.
- e) A primitive-type variable can be used to invoke a method.
- f) Variables declared in the body of a particular method are known as instance variables and can be used in all methods of the class.
- g) Every method's body is delimited by left and right braces (`{` and `}`).
- h) Primitive-type local variables are initialized by default.
- i) Reference-type instance variables are initialized by default to the value `null`.
- j) Any class that contains `public static void main( String[] args )` can be used to execute an application.
- k) The number of arguments in the method call must match the number of parameters in the method declaration's parameter list.
- l) Floating-point values that appear in source code are known as floating-point literals and are type `float` by default.

**3.3** What is the difference between a local variable and a field?

**3.4** Explain the purpose of a method parameter. What is the difference between a parameter and an argument?

## Answers to Self-Review Exercises

**3.1** a) `public`. b) `class`. c) `new`. d) type, name. e) default package. f) instance variable. g) `float`, `double`. h) double-precision. i) `nextDouble`. j) modifier. k) `void`. l) `nextLine`. m) `java.lang`. n) `import` declaration. o) floating-point number. p) single-precision. q) `%f`. r) primitive, reference.

**3.2** a) False. By convention, method names begin with a lowercase first letter and all subsequent words in the name begin with a capital first letter. b) True. c) True. d) True. e) False. A prim-

itive-type variable cannot be used to invoke a method—a reference to an object is required to invoke the object's methods. f) False. Such variables are called local variables and can be used only in the method in which they're declared. g) True. h) False. Primitive-type instance variables are initialized by default. Each local variable must explicitly be assigned a value. i) True. j) True. k) True. l) False. Such literals are of type `double` by default.

**3.3** A local variable is declared in the body of a method and can be used only from the point at which it's declared through the end of the method declaration. A field is declared in a class, but not in the body of any of the class's methods. Also, fields are accessible to all methods of the class. (We'll see an exception to this in Chapter 8, *Classes and Objects: A Deeper Look*.)

**3.4** A parameter represents additional information that a method requires to perform its task. Each parameter required by a method is specified in the method's declaration. An argument is the actual value for a method parameter. When a method is called, the argument values are passed to the corresponding parameters of the method so that it can perform its task.

## Exercises

**3.5** (*Keyword new*) What's the purpose of keyword `new`? Explain what happens when you use it.

**3.6** (*Default Constructors*) What is a default constructor? How are an object's instance variables initialized if a class has only a default constructor?

**3.7** (*Instance Variables*) Explain the purpose of an instance variable.

**3.8** (*Using Classes Without Importing Them*) Most classes need to be imported before they can be used in an application. Why is every application allowed to use classes `System` and `String` without first importing them?

**3.9** (*Using a Class Without Importing It*) Explain how a program could use class `Scanner` without importing it.

**3.10** (*set and get Methods*) Explain why a class might provide a *set* method and a *get* method for an instance variable.

**3.11** (*Modified GradeBook Class*) Modify class `GradeBook` (Fig. 3.10) as follows:

- Include a `String` instance variable that represents the name of the course's instructor.
- Provide a *set* method to change the instructor's name and a *get* method to retrieve it.
- Modify the constructor to specify two parameters—one for the course name and one for the instructor's name.
- Modify method `displayMessage` to output the welcome message and course name, followed by "This course is presented by: " and the instructor's name.

Use your modified class in a test application that demonstrates the class's new capabilities.

**3.12** (*Modified Account Class*) Modify class `Account` (Fig. 3.13) to provide a method called *debit* that withdraws money from an `Account`. Ensure that the debit amount does not exceed the `Account`'s balance. If it does, the balance should be left unchanged and the method should print a message indicating "Debit amount exceeded account balance." Modify class `AccountTest` (Fig. 3.14) to test method *debit*.

**3.13** (*Invoice Class*) Create a class called `Invoice` that a hardware store might use to represent an invoice for an item sold at the store. An `Invoice` should include four pieces of information as instance variables—a part number (type `String`), a part description (type `String`), a quantity of the item being purchased (type `int`) and a price per item (type `double`). Your class should have a constructor that initializes the four instance variables. Provide a *set* and a *get* method for each instance variable. In addition, provide a method named `getInvoiceAmount` that calculates the invoice amount (i.e., multiplies the quantity by the price per item), then returns the amount as a `double` value. If the

quantity is not positive, it should be set to 0. If the price per item is not positive, it should be set to 0.0. Write a test application named `InvoiceTest` that demonstrates class `Invoice`'s capabilities.

**3.14 (Employee Class)** Create a class called `Employee` that includes three instance variables—a first name (type `String`), a last name (type `String`) and a monthly salary (double). Provide a constructor that initializes the three instance variables. Provide a *set* and a *get* method for each instance variable. If the monthly salary is not positive, do not set its value. Write a test application named `EmployeeTest` that demonstrates class `Employee`'s capabilities. Create two `Employee` objects and display each object's *yearly* salary. Then give each `Employee` a 10% raise and display each `Employee`'s yearly salary again.

**3.15 (Date Class)** Create a class called `Date` that includes three instance variables—a month (type `int`), a day (type `int`) and a year (type `int`). Provide a constructor that initializes the three instance variables and assumes that the values provided are correct. Provide a *set* and a *get* method for each instance variable. Provide a method `displayDate` that displays the month, day and year separated by forward slashes (/). Write a test application named `DateTest` that demonstrates class `Date`'s capabilities.

## Making a Difference

**3.16 (Target-Heart-Rate Calculator)** While exercising, you can use a heart-rate monitor to see that your heart rate stays within a safe range suggested by your trainers and doctors. According to the American Heart Association (AHA) ([www.americanheart.org/presenter.jhtml?identifier=4736](http://www.americanheart.org/presenter.jhtml?identifier=4736)), the formula for calculating your *maximum heart rate* in beats per minute is 220 minus your age in years. Your *target heart rate* is a range that's 50–85% of your maximum heart rate. [Note: These formulas are estimates provided by the AHA. Maximum and target heart rates may vary based on the health, fitness and gender of the individual. Always consult a physician or qualified health care professional before beginning or modifying an exercise program.] Create a class called `HeartRates`. The class attributes should include the person's first name, last name and date of birth (consisting of separate attributes for the month, day and year of birth). Your class should have a constructor that receives this data as parameters. For each attribute provide *set* and *get* methods. The class also should include a method that calculates and returns the person's age (in years), a method that calculates and returns the person's maximum heart rate and a method that calculates and returns the person's target heart rate. Write a Java application that prompts for the person's information, instantiates an object of class `HeartRates` and prints the information from that object—including the person's first name, last name and date of birth—then calculates and prints the person's age in (years), maximum heart rate and target-heart-rate range.

**3.17 (Computerization of Health Records)** A health care issue that has been in the news lately is the computerization of health records. This possibility is being approached cautiously because of sensitive privacy and security concerns, among others. [We address such concerns in later exercises.] Computerizing health records could make it easier for patients to share their health profiles and histories among their various health care professionals. This could improve the quality of health care, help avoid drug conflicts and erroneous drug prescriptions, reduce costs and, in emergencies, could save lives. In this exercise, you'll design a “starter” `HealthProfile` class for a person. The class attributes should include the person's first name, last name, gender, date of birth (consisting of separate attributes for the month, day and year of birth), height (in inches) and weight (in pounds). Your class should have a constructor that receives this data. For each attribute, provide *set* and *get* methods. The class also should include methods that calculate and return the user's age in years, maximum heart rate and target-heart-rate range (see Exercise 3.16), and body mass index (BMI; see Exercise 2.33). Write a Java application that prompts for the person's information, instantiates an object of class `HealthProfile` for that person and prints the information from that object—including the person's first name, last name, gender, date of birth, height and weight—then calculates and prints the person's age in years, BMI, maximum heart rate and target-heart-rate range. It should also display the BMI values chart from Exercise 2.33.

## Control Statements: Part I

*Let's all move one place on.*

—Lewis Carroll

*The wheel is come full circle.*

—William Shakespeare

*How many apples fell on  
Newton's head before he took the  
hint!*

—Robert Frost

### Objectives

In this chapter you'll learn:

- Basic problem-solving techniques.
- To develop algorithms through the process of top-down, stepwise refinement.
- To use the `if` and `if...else` selection statements to choose among alternative actions.
- To use the `while` repetition statement to execute statements in a program repeatedly.
- To use counter-controlled repetition and sentinel-controlled repetition.
- To use the compound assignment, increment and decrement operators.
- The portability of primitive data types.

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference*

## 4.1 Introduction

Before writing a program to solve a problem, you should have a thorough understanding of the problem and a carefully planned approach to solving it. When writing a program, you also should understand the available building blocks and employ proven program-construction techniques. In this chapter and in Chapter 5, Control Statements: Part 2, we discuss these issues in our presentation of the theory and principles of structured programming. The concepts presented here are crucial in building classes and manipulating objects.

We introduce Java’s `if`, `if...else` and `while` statements, three of the building blocks that allow you to specify the logic required for methods to perform their tasks. We devote a portion of this chapter (and Chapters 5 and 7) to further developing the `GradeBook` class introduced in Chapter 3. In particular, we add a method to the `GradeBook` class that uses control statements to calculate the average of a set of student grades. Another example demonstrates additional ways to combine control statements to solve a similar problem. We introduce Java’s compound assignment, increment and decrement operators. Finally, we discuss the portability of Java’s primitive types.

## 4.2 Algorithms

Any computing problem can be solved by executing a series of actions in a specific order. A procedure for solving a problem in terms of

1. the **actions** to execute and
2. the **order** in which these actions execute

is called an **algorithm**. The following example demonstrates that correctly specifying the order in which the actions execute is important.

Consider the “rise-and-shine algorithm” followed by one executive for getting out of bed and going to work: (1) Get out of bed; (2) take off pajamas; (3) take a shower; (4) get dressed; (5) eat breakfast; (6) carpool to work. This routine gets the executive to work well prepared to make critical decisions. Suppose that the same steps are performed in a slightly different order: (1) Get out of bed; (2) take off pajamas; (3) get dressed; (4) take a shower; (5) eat breakfast; (6) carpool to work. In this case, our executive shows up for work soaking

wet. Specifying the order in which statements (actions) execute in a program is called **program control**. This chapter investigates program control using Java's **control statements**.

### 4.3 Pseudocode

**Pseudocode** is an informal language that helps you develop algorithms without having to worry about the strict details of Java language syntax. The pseudocode we present is particularly useful for developing algorithms that will be converted to structured portions of Java programs. Pseudocode is similar to everyday English—it's convenient and user friendly, but it's not an actual computer programming language. You'll see an algorithm written in pseudocode in Fig. 4.5.

Pseudocode does not execute on computers. Rather, it helps you “think out” a program before attempting to write it in a programming language, such as Java. This chapter provides several examples of using pseudocode to develop Java programs.

The style of pseudocode we present consists purely of characters, so you can type pseudocode conveniently, using any text-editor program. A carefully prepared pseudocode program can easily be converted to a corresponding Java program.

Pseudocode normally describes only statements representing the actions that occur after you convert a program from pseudocode to Java and the program is run on a computer. Such actions might include input, output or calculations. We typically do not include variable declarations in our pseudocode, but some programmers choose to list variables and mention their purposes at the beginning of their pseudocode.

### 4.4 Control Structures

Normally, statements in a program are executed one after the other in the order in which they're written. This process is called **sequential execution**. Various Java statements, which we'll soon discuss, enable you to specify that the next statement to execute is *not* necessarily the *next* one in sequence. This is called **transfer of control**.

During the 1960s, it became clear that the indiscriminate use of transfers of control was the root of much difficulty experienced by software development groups. The blame was pointed at the **goto statement** (used in most programming languages of the time), which allows you to specify a transfer of control to one of a wide range of destinations in a program. The term **structured programming** became almost synonymous with “goto elimination.” [Note: Java does *not* have a goto statement; however, the word goto is *reserved* by Java and should *not* be used as an identifier in programs.]

The research of Bohm and Jacopini<sup>1</sup> had demonstrated that programs could be written *without* any goto statements. The challenge of the era for programmers was to shift their styles to “goto-less programming.” Not until the 1970s did most programmers start taking structured programming seriously. The results were impressive. Software development groups reported shorter development times, more frequent on-time delivery of systems and more frequent within-budget completion of software projects. The key to these successes was that structured programs were clearer, easier to debug and modify, and more likely to be bug free in the first place.

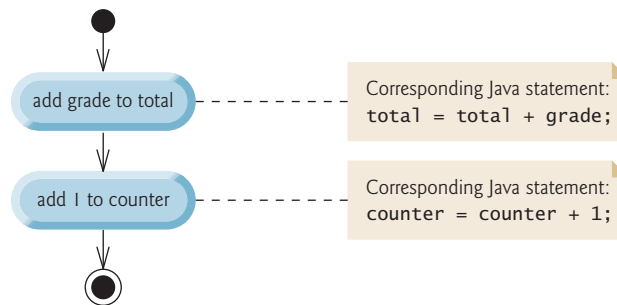

---

1. Bohm, C., and G. Jacopini, “Flow Diagrams, Turing Machines, and Languages with Only Two Formation Rules,” *Communications of the ACM*, Vol. 9, No. 5, May 1966, pp. 336–371.

Bohm and Jacopini’s work demonstrated that all programs could be written in terms of only three control structures—the **sequence structure**, the **selection structure** and the **repetition structure**. When we introduce Java’s control structure implementations, we’ll refer to them in the terminology of the *Java Language Specification* as “control statements.”

### Sequence Structure in Java

The sequence structure is built into Java. Unless directed otherwise, the computer executes Java statements one after the other in the order in which they’re written—that is, in sequence. The **activity diagram** in Fig. 4.1 illustrates a typical sequence structure in which two calculations are performed in order. Java lets you have as many actions as you want in a sequence structure. As we’ll soon see, anywhere a single action may be placed, we may place several actions in sequence.

**Fig. 4.1** | Sequence structure activity diagram.

A UML activity diagram models the **workflow** (also called the **activity**) of a portion of a software system. Such workflows may include a portion of an algorithm, like the sequence structure in Fig. 4.1. Activity diagrams are composed of symbols, such as **action-state symbols** (rectangles with their left and right sides replaced with outward arcs), **diamonds** and **small circles**. These symbols are connected by **transition arrows**, which represent the flow of the activity—that is, the order in which the actions should occur.

Like pseudocode, activity diagrams help you develop and represent algorithms, although many programmers prefer pseudocode. Activity diagrams clearly show how control structures operate. We use the UML in this chapter and Chapter 5 to show control flow in control statements. In Chapters 12–13, we use the UML in a real-world automated-teller machine case study.

Consider the sequence structure activity diagram in Fig. 4.1. It contains two **action states** that represent actions to perform. Each action state contains an **action expression**—for example, “add grade to total” or “add 1 to counter”—that specifies a particular action to perform. Other actions might include calculations or input/output operations. The arrows in the activity diagram represent **transitions**, which indicate the *order* in which the actions represented by the action states occur. The program that implements the activities illustrated by the diagram in Fig. 4.1 first adds grade to `total`, then adds 1 to counter.

The **solid circle** at the top of the activity diagram represents the **initial state**—the *beginning* of the workflow *before* the program performs the modeled actions. The **solid**

circle surrounded by a hollow circle that appears at the bottom of the diagram represents the **final state**—the *end* of the workflow *after* the program performs its actions.

Figure 4.1 also includes rectangles with the upper-right corners folded over. These are UML **notes** (like comments in Java)—explanatory remarks that describe the purpose of symbols in the diagram. Figure 4.1 uses UML notes to show the Java code associated with each action state. A **dotted line** connects each note with the element it describes. Activity diagrams normally do *not* show the Java code that implements the activity. We do this here to illustrate how the diagram relates to Java code. For more information on the UML, see our optional case study (Chapters 12–13) or visit [www.uml.org](http://www.uml.org).

### Selection Statements in Java

Java has three types of **selection statements** (discussed in this chapter and Chapter 5). The `if` statement either performs (selects) an action, if a condition is true, or skips it, if the condition is false. The `if...else` statement performs an action if a condition is true and performs a different action if the condition is false. The `switch` statement (Chapter 5) performs one of many different actions, depending on the value of an expression.

The `if` statement is a **single-selection statement** because it selects or ignores a *single* action (or, as we'll soon see, a *single group of actions*). The `if...else` statement is called a **double-selection statement** because it selects between *two different actions* (or *groups of actions*). The `switch` statement is called a **multiple-selection statement** because it selects among *many different actions* (or *groups of actions*).

### Repetition Statements in Java

Java provides three **repetition statements** (also called **looping statements**) that enable programs to perform statements repeatedly as long as a condition (called the **loop-continuation condition**) remains true. The repetition statements are the `while`, `do...while` and `for` statements. (Chapter 5 presents the `do...while` and `for` statements.) The `while` and `for` statements perform the action (or group of actions) in their bodies zero or more times—if the loop-continuation condition is initially false, the action (or group of actions) will not execute. The `do...while` statement performs the action (or group of actions) in its body *one or more* times. The words `if`, `else`, `switch`, `while`, `do` and `for` are Java keywords. A complete list of Java keywords appears in Appendix C.

### Summary of Control Statements in Java

Java has only three kinds of control structures, which from this point forward we refer to as control statements: the sequence statement, selection statements (three types) and repetition statements (three types). Every program is formed by combining as many of these statements as is appropriate for the algorithm the program implements. We can model each control statement as an activity diagram. Like Fig. 4.1, each diagram contains an initial state and a final state that represent a control statement's entry point and exit point, respectively. **Single-entry/single-exit control statements** make it easy to build programs—we simply connect the exit point of one to the entry point of the next. We call this **control-statement stacking**. We'll learn that there's only one other way in which control statements may be connected—**control-statement nesting**—in which one control statement appears *inside* another. Thus, algorithms in Java programs are constructed from only three kinds of control statements, combined in only two ways. This is the essence of simplicity.

## 4.5 if Single-Selection Statement

Programs use selection statements to choose among alternative courses of action. For example, suppose that the passing grade on an exam is 60. The pseudocode statement

```
If student's grade is greater than or equal to 60
  Print "Passed"
```

determines whether the condition “student’s grade is greater than or equal to 60” is true. If so, “Passed” is printed, and the next pseudocode statement in order is “performed.” (Remember, pseudocode is not a real programming language.) If the condition is false, the *Print* statement is ignored, and the next pseudocode statement in order is performed. The indentation of the second line of this selection statement is optional, but recommended, because it emphasizes the inherent structure of structured programs.

The preceding pseudocode *If* statement may be written in Java as

```
if ( studentGrade >= 60 )
    System.out.println( "Passed" );
```

The Java code corresponds closely to the pseudocode. This is one of the properties of pseudocode that makes it such a useful program development tool.

Figure 4.2 illustrates the single-selection *if* statement. This figure contains the most important symbol in an activity diagram—the diamond, or **decision symbol**, which indicates that a decision is to be made. The workflow continues along a path determined by the symbol’s associated **guard conditions**, which can be true or false. Each transition arrow emerging from a decision symbol has a guard condition (specified in square brackets next to the arrow). If a guard condition is true, the workflow enters the action state to which the transition arrow points. In Fig. 4.2, if the grade is greater than or equal to 60, the program prints “Passed,” then transitions to the activity’s final state. If the grade is less than 60, the program immediately transitions to the final state without displaying a message.

**Fig. 4.2** | *if* single-selection statement UML activity diagram.

The *if* statement is a single-entry/single-exit control statement. We’ll see that the activity diagrams for the remaining control statements also contain initial states, transition arrows, action states that indicate actions to perform, decision symbols (with associated guard conditions) that indicate decisions to be made, and final states.

## 4.6 if...else Double-Selection Statement

The *if* single-selection statement performs an indicated action only when the condition is true; otherwise, the action is skipped. The **if...else double-selection statement** allows

you to specify an action to perform when the condition is true and a different action when the condition is false. For example, the pseudocode statement

```
If student's grade is greater than or equal to 60
    Print "Passed"
Else
    Print "Failed"
```

prints “Passed” if the student’s grade is greater than or equal to 60, but prints “Failed” if it’s less than 60. In either case, after printing occurs, the next pseudocode statement in sequence is “performed.”

The preceding *If...Else* pseudocode statement can be written in Java as

```
if ( grade >= 60 )
    System.out.println( "Passed" );
else
    System.out.println( "Failed" );
```

The body of the `else` is also indented. Whatever indentation convention you choose should be applied consistently throughout your programs.

#### Good Programming Practice 4.1

*Indent both body statements of an `if...else` statement. Many IDEs do this for you.*

#### Good Programming Practice 4.2

*If there are several levels of indentation, each level should be indented the same additional amount of space.*

Figure 4.3 illustrates the flow of control in the `if...else` statement. Once again, the symbols in the UML activity diagram (besides the initial state, transition arrows and final state) represent action states and decisions.

**Fig. 4.3** | `if...else` double-selection statement UML activity diagram.

### Conditional Operator (?:)

Java provides the **conditional operator** (`?:`) that can be used in place of an `if...else` statement. This is Java’s only **ternary operator** (operator that takes three operands). Together, the operands and the `?:` symbol form a **conditional expression**. The first operand (to the left of the `?`) is a **boolean expression** (i.e., a condition that evaluates to a boolean

value—**true** or **false**), the second operand (between the ? and :) is the value of the conditional expression if the boolean expression is true and the third operand (to the right of the :) is the value of the conditional expression if the boolean expression evaluates to false. For example, the statement

```
System.out.println( studentGrade >= 60 ? "Passed" : "Failed" );
```

prints the value of `println`'s conditional-expression argument. The conditional expression in this statement evaluates to the string "Passed" if the boolean expression `studentGrade >= 60` is true and to the string "Failed" if it's false. Thus, this statement with the conditional operator performs essentially the same function as the `if...else` statement shown earlier in this section. The precedence of the conditional operator is low, so the entire conditional expression is normally placed in parentheses. We'll see that conditional expressions can be used in some situations where `if...else` statements cannot.

### Nested if...else Statements

A program can test multiple cases by placing `if...else` statements inside other `if...else` statements to create **nested if...else statements**. For example, the following pseudocode represents a nested `if...else` that prints A for exam grades greater than or equal to 90, B for grades 80 to 89, C for grades 70 to 79, D for grades 60 to 69 and F for all other grades:

```
If student's grade is greater than or equal to 90
  Print "A"
else
  If student's grade is greater than or equal to 80
    Print "B"
  else
    If student's grade is greater than or equal to 70
      Print "C"
    else
      If student's grade is greater than or equal to 60
        Print "D"
      else
        Print "F"
```

This pseudocode may be written in Java as

```
if ( studentGrade >= 90 )
    System.out.println( "A" );
else
    if ( studentGrade >= 80 )
        System.out.println( "B" );
    else
        if ( studentGrade >= 70 )
            System.out.println( "C" );
        else
            if ( studentGrade >= 60 )
                System.out.println( "D" );
            else
                System.out.println( "F" );
```

If variable `studentGrade` is greater than or equal to 90, the first four conditions in the nested `if...else` statement will be true, but only the statement in the `if` part of the first `if...else` statement will execute. After that statement executes, the `else` part of the “outermost” `if...else` statement is skipped. Many programmers prefer to write the preceding nested `if...else` statement as

```
if ( studentGrade >= 90 )
    System.out.println( "A" );
else if ( studentGrade >= 80 )
    System.out.println( "B" );
else if ( studentGrade >= 70 )
    System.out.println( "C" );
else if ( studentGrade >= 60 )
    System.out.println( "D" );
else
    System.out.println( "F" );
```

The two forms are identical except for the spacing and indentation, which the compiler ignores. The latter form avoids deep indentation of the code to the right. Such indentation often leaves little room on a line of source code, forcing lines to be split.

### *Dangling-else Problem*

The Java compiler always associates an `else` with the immediately preceding `if` unless told to do otherwise by the placement of braces (`{` and `}`). This behavior can lead to what is referred to as the **dangling-else problem**. For example,

```
if ( x > 5 )
    if ( y > 5 )
        System.out.println( "x and y are > 5" );
else
    System.out.println( "x is <= 5" );
```

appears to indicate that if `x` is greater than 5, the nested `if` statement determines whether `y` is also greater than 5. If so, the string “`x and y are > 5`” is output. Otherwise, it appears that if `x` is not greater than 5, the `else` part of the `if...else` outputs the string “`x is <= 5`”. Beware! This nested `if...else` statement does not execute as it appears. The compiler actually interprets the statement as

```
if ( x > 5 )
    if ( y > 5 )
        System.out.println( "x and y are > 5" );
else
    System.out.println( "x is <= 5" );
```

in which the body of the first `if` is a nested `if...else`. The outer `if` statement tests whether `x` is greater than 5. If so, execution continues by testing whether `y` is also greater than 5. If the second condition is true, the proper string—“`x and y are > 5`”—is displayed. However, if the second condition is false, the string “`x is <= 5`” is displayed, even though we know that `x` is greater than 5. Equally bad, if the outer `if` statement’s condition is false, the inner `if...else` is skipped and nothing is displayed.

To force the nested `if...else` statement to execute as it was originally intended, we must write it as follows:

```

if ( x > 5 )
{
    if ( y > 5 )
        System.out.println( "x and y are > 5" );
}
else
    System.out.println( "x is <= 5" );

```

The braces indicate that the second `if` is in the body of the first and that the `else` is associated with the *first* `if`. Exercises 4.27–4.28 investigate the dangling-else problem further.

### Blocks

The `if` statement normally expects only one statement in its body. To include several statements in the body of an `if` (or the body of an `else` for an `if...else` statement), enclose the statements in braces. Statements contained in a pair of braces form a **block**. A block can be placed anywhere in a program that a single statement can be placed.

The following example includes a block in the `else` part of an `if...else` statement:

```

if ( grade >= 60 )
    System.out.println( "Passed" );
else
{
    System.out.println( "Failed" );
    System.out.println( "You must take this course again." );
}

```

In this case, if grade is less than 60, the program executes *both* statements in the body of the `else` and prints

```

Failed
You must take this course again.

```

Note the braces surrounding the two statements in the `else` clause. These braces are important. Without the braces, the statement

```

System.out.println( "You must take this course again." );

```

would be outside the body of the `else` part of the `if...else` statement and would execute *regardless* of whether the grade was less than 60.

Syntax errors (e.g., when one brace in a block is left out of the program) are caught by the compiler. A **logic error** (e.g., when both braces in a block are left out of the program) has its effect at execution time. A **fatal logic error** causes a program to fail and terminate prematurely. A **nonfatal logic error** allows a program to continue executing but causes it to produce incorrect results.

Just as a block can be placed anywhere a single statement can be placed, it's also possible to have an empty statement. Recall from Section 2.8 that the empty statement is represented by placing a semicolon (;) where a statement would normally be.

### Common Programming Error 4.1

Placing a semicolon after the condition in an `if` or `if...else` statement leads to a logic error in single-selection `if` statements and a syntax error in double-selection `if...else` statements (when the `if`-part contains an actual body statement).

## 4.7 while Repetition Statement

A **repetition** (or **looping**) **statement** allows you to specify that a program should repeat an action while some condition remains true. The pseudocode statement

*While there are more items on my shopping list  
Purchase next item and cross it off my list*

describes the repetition that occurs during a shopping trip. The condition “there are more items on my shopping list” may be true or false. If it’s true, then the action “Purchase next item and cross it off my list” is performed. This action will be performed repeatedly while the condition remains true. The statement(s) contained in the *While* repetition statement constitute its body, which may be a single statement or a block. Eventually, the condition will become false (when the last item on the shopping list has been purchased and crossed off). At this point, the repetition terminates, and the first statement after the repetition statement executes.

As an example of Java’s **while repetition statement**, consider a program segment that finds the first power of 3 larger than 100. Suppose that the `int` variable `product` is initialized to 3. After the following `while` statement executes, `product` contains the result:

```
while ( product <= 100 )
    product = 3 * product;
```

When this `while` statement begins execution, the value of variable `product` is 3. Each iteration of the `while` statement multiplies `product` by 3, so `product` takes on the values 9, 27, 81 and 243 successively. When variable `product` becomes 243, the `while`-statement condition—`product <= 100`—becomes false. This terminates the repetition, so the final value of `product` is 243. At this point, program execution continues with the next statement after the `while` statement.

### Common Programming Error 4.2

*Not providing in the body of a `while` statement an action that eventually causes the condition in the `while` to become false normally results in a logic error called an **infinite loop** (the loop never terminates).*

The UML activity diagram in Fig. 4.4 illustrates the flow of control in the preceding `while` statement. Once again, the symbols in the diagram (besides the initial state, transition arrows, a final state and three notes) represent an action state and a decision. This diagram introduces the UML’s **merge symbol**. The UML represents both the merge symbol and the decision symbol as diamonds. The merge symbol joins two flows of activity into one. In this diagram, the merge symbol joins the transitions from the initial state and from the action state, so they both flow into the decision that determines whether the loop should begin (or continue) executing. The decision and merge symbols can be distinguished by the number of “incoming” and “outgoing” transition arrows. A decision symbol has one transition arrow pointing to the diamond and two or more pointing out from it to indicate possible transitions from that point. In addition, each transition arrow pointing out of a decision symbol has a guard condition next to it. A merge symbol has two or more transition arrows pointing to the diamond and only one pointing from the diamond, to indicate multiple activity flows merging to continue the activity. *None* of the transition arrows associated with a merge symbol has a guard condition.

**Fig. 4.4** | while repetition statement UML activity diagram.

Figure 4.4 clearly shows the repetition of the while statement discussed earlier in this section. The transition arrow emerging from the action state points back to the merge, from which program flow transitions back to the decision that's tested at the beginning of each iteration of the loop. The loop continues to execute until the guard condition `product > 100` becomes true. Then the while statement exits (reaches its final state), and control passes to the next statement in sequence in the program.

## 4.8 Formulating Algorithms: Counter-Controlled Repetition

To illustrate how algorithms are developed, we modify the GradeBook class of Chapter 3 to solve two variations of a problem that averages student grades. Consider the following problem statement:

*A class of ten students took a quiz. The grades (integers in the range 0 to 100) for this quiz are available to you. Determine the class average on the quiz.*

The class average is equal to the sum of the grades divided by the number of students. The algorithm for solving this problem on a computer must input each grade, keep track of the total of all grades input, perform the averaging calculation and print the result.

### *Pseudocode Algorithm with Counter-Controlled Repetition*

Let's use pseudocode to list the actions to execute and specify the order in which they should execute. We use **counter-controlled repetition** to input the grades one at a time. This technique uses a variable called a **counter** (or **control variable**) to control the number of times a set of statements will execute. Counter-controlled repetition is often called **definite repetition**, because the number of repetitions is known *before* the loop begins executing. In this example, repetition terminates when the counter exceeds 10. This section presents a fully developed pseudocode algorithm (Fig. 4.5) and a version of class GradeBook (Fig. 4.6) that implements the algorithm in a Java method. We then present an application (Fig. 4.7) that demonstrates the algorithm in action. In Section 4.9, we demonstrate how to use pseudocode to develop such an algorithm from scratch.

### Software Engineering Observation 4.1

*Experience has shown that the most difficult part of solving a problem on a computer is developing the algorithm for the solution. Once a correct algorithm has been specified, producing a working Java program from the algorithm is usually straightforward.*

Note the references in the algorithm of Fig. 4.5 to a total and a counter. A **total** is a variable used to accumulate the sum of several values. A counter is a variable used to count—in this case, the grade counter indicates which of the 10 grades is about to be entered by the user. Variables used to store totals are normally initialized to zero before being used in a program.

- 1 *Set total to zero*
- 2 *Set grade counter to one*
- 3
- 4 *While grade counter is less than or equal to ten*
- 5 *Prompt the user to enter the next grade*
- 6 *Input the next grade*
- 7 *Add the grade into the total*
- 8 *Add one to the grade counter*
- 9
- 10 *Set the class average to the total divided by ten*
- 11 *Print the class average*

**Fig. 4.5** | Pseudocode algorithm that uses counter-controlled repetition to solve the class-average problem.

### Implementing Counter-Controlled Repetition in Class `GradeBook`

Class `GradeBook` (Fig. 4.6) contains a constructor (lines 11–14) that assigns a value to the class’s instance variable `courseName` (declared in line 8). Lines 17–20, 23–26 and 29–34 declare methods `setCourseName`, `getCourseName` and `displayMessage`, respectively. Lines 37–66 declare method `determineClassAverage`, which implements the class-averaging algorithm described by the pseudocode in Fig. 4.5.

Line 40 declares and initializes `Scanner` variable `input`, which is used to read values entered by the user. Lines 42–45 declare local variables `total`, `gradeCounter`, `grade` and `average` to be of type `int`. Variable `grade` stores the user input.

```

1 // Fig. 4.6: GradeBook.java
2 // GradeBook class that solves class-average problem using
3 // counter-controlled repetition.
4 import java.util.Scanner; // program uses class Scanner
5
6 public class GradeBook
7 {
8     private String courseName; // name of course this GradeBook represents

```

**Fig. 4.6** | `GradeBook` class that solves class-average problem using counter-controlled repetition. (Part I of 3.)

```
9
10 // constructor initializes courseName
11 public GradeBook( String name )
12 {
13     courseName = name; // initializes courseName
14 } // end constructor
15
16 // method to set the course name
17 public void setCourseName( String name )
18 {
19     courseName = name; // store the course name
20 } // end method setCourseName
21
22 // method to retrieve the course name
23 public String getCourseName()
24 {
25     return courseName;
26 } // end method getCourseName
27
28 // display a welcome message to the GradeBook user
29 public void displayMessage()
30 {
31     // getCourseName gets the name of the course
32     System.out.printf( "Welcome to the grade book for\n%s!\n\n",
33         getCourseName() );
34 } // end method displayMessage
35
36 // determine class average based on 10 grades entered by user
37 public void determineClassAverage()
38 {
39     // create Scanner to obtain input from command window
40     Scanner input = new Scanner( System.in );
41
42     int total; // sum of grades entered by user
43     int gradeCounter; // number of the grade to be entered next
44     int grade; // grade value entered by user
45     int average; // average of grades
46
47     // initialization phase
48     total = 0; // initialize total
49     gradeCounter = 1; // initialize loop counter
50
51     // processing phase uses counter-controlled repetition
52     while ( gradeCounter <= 10 ) // loop 10 times
53     {
54         System.out.print( "Enter grade: " ); // prompt
55         grade = input.nextInt(); // input next grade
56         total = total + grade; // add grade to total
57         gradeCounter = gradeCounter + 1; // increment counter by 1
58     } // end while
59
```

**Fig. 4.6** | GradeBook class that solves class-average problem using counter-controlled repetition. (Part 2 of 3.)

```

60     // termination phase
61     average = total / 10; // integer division yields integer result
62
63     // display total and average of grades
64     System.out.printf( "\nTotal of all 10 grades is %d\n", total );
65     System.out.printf( "Class average is %d\n", average );
66 } // end method determineClassAverage
67 } // end class GradeBook

```

**Fig. 4.6** | GradeBook class that solves class-average problem using counter-controlled repetition. (Part 3 of 3.)

The declarations (in lines 42–45) appear in the body of method `determineClassAverage`. Recall that variables declared in a method body are local variables and can be used only from the line of their declaration to the closing right brace of the method declaration. A local variable’s declaration must appear before the variable is used in that method. A local variable cannot be accessed outside the method in which it’s declared.

In this chapter, class `GradeBook` simply reads and processes a set of grades. The averaging calculation is performed in method `determineClassAverage` using local variables—we do not preserve any information about student grades in instance variables of the class.

The assignments (in lines 48–49) initialize `total` to 0 and `gradeCounter` to 1. These initializations occur *before* the variables are used in calculations. Variables `grade` and `average` (for the user input and calculated average, respectively) need not be initialized here—their values will be assigned as they’re input or calculated later in the method.

### Common Programming Error 4.3

*Using the value of a local variable before it’s initialized results in a compilation error. All local variables must be initialized before their values are used in expressions.*

### Error-Prevention Tip 4.1

*Initialize each counter and total, either in its declaration or in an assignment statement. Totals are normally initialized to 0. Counters are normally initialized to 0 or 1, depending on how they’re used (we’ll show examples of when to use 0 and when to use 1).*

Line 52 indicates that the `while` statement should continue looping (also called **iterating**) as long as `gradeCounter`’s value is less than or equal to 10. While this condition remains true, the `while` statement repeatedly executes the statements between the braces that delimit its body (lines 54–57).

Line 54 displays the prompt "Enter grade: ". Line 55 reads the grade entered by the user and assigns it to variable `grade`. Then line 56 adds the new grade entered by the user to the `total` and assigns the result to `total`, which replaces its previous value.

Line 57 adds 1 to `gradeCounter` to indicate that the program has processed a grade and is ready to input the next grade from the user. Incrementing `gradeCounter` eventually causes it to exceed 10. Then the loop terminates, because its condition (line 52) becomes false.

When the loop terminates, line 61 performs the averaging calculation and assigns its result to the variable `average`. Line 64 uses `System.out.printf` method to display the

text "Total of all 10 grades is " followed by variable `total`'s value. Line 65 then uses `printf` to display the text "Class average is " followed by variable `average`'s value. After reaching line 66, method `determineClassAverage` returns control to the calling method (i.e., `main` in `GradeBookTest` of Fig. 4.7).

### *Class GradeBookTest*

Class `GradeBookTest` (Fig. 4.7) creates an object of class `GradeBook` (Fig. 4.6) and demonstrates its capabilities. Lines 10–11 of Fig. 4.7 create a new `GradeBook` object and assign it to variable `myGradeBook`. The `String` in line 11 is passed to the `GradeBook` constructor (lines 11–14 of Fig. 4.6). Line 13 calls `myGradeBook`'s `displayMessage` method to display a welcome message to the user. Line 14 then calls `myGradeBook`'s `determineClassAverage` method to allow the user to enter 10 grades, for which the method then calculates and prints the average—the method performs the algorithm shown in Fig. 4.5.

```

1 // Fig. 4.7: GradeBookTest.java
2 // Create GradeBook object and invoke its determineClassAverage method.
3
4 public class GradeBookTest
5 {
6     public static void main( String[] args )
7     {
8         // create GradeBook object myGradeBook and
9         // pass course name to constructor
10        GradeBook myGradeBook = new GradeBook(
11            "CS101 Introduction to Java Programming" );
12
13        myGradeBook.displayMessage(); // display welcome message
14        myGradeBook.determineClassAverage(); // find average of 10 grades
15    } // end main
16 } // end class GradeBookTest

```

```

Welcome to the grade book for
CS101 Introduction to Java Programming!

```

```

Enter grade: 67
Enter grade: 78
Enter grade: 89

Enter grade: 82
Enter grade: 100

```

```

Total of all 10 grades is 846
Class average is 84

```

**Fig. 4.7** | `GradeBookTest` class creates an object of class `GradeBook` (Fig. 4.6) and invokes its `determineClassAverage` method.

*Notes on Integer Division and Truncation*

The averaging calculation performed by method `determineClassAverage` in response to the method call at line 14 in Fig. 4.7 produces an integer result. The program's output indicates that the sum of the grade values in the sample execution is 846, which, when divided by 10, should yield the floating-point number 84.6. However, the result of the calculation `total / 10` (line 61 of Fig. 4.6) is the integer 84, because `total` and 10 are both integers. Dividing two integers results in **integer division**—any fractional part of the calculation is lost (i.e., **truncated**). In the next section we'll see how to obtain a floating-point result from the averaging calculation.

**Common Programming Error 4.4**

*Assuming that integer division rounds (rather than truncates) can lead to incorrect results. For example,  $7 \div 4$ , which yields 1.75 in conventional arithmetic, truncates to 1 in integer arithmetic, rather than rounding to 2.*

## 4.9 Formulating Algorithms: Sentinel-Controlled Repetition

Let's generalize Section 4.8's class-average problem. Consider the following problem:

*Develop a class-averaging program that processes grades for an arbitrary number of students each time it's run.*

In the previous class-average example, the problem statement specified the number of students, so the number of grades (10) was known in advance. In this example, no indication is given of how many grades the user will enter during the program's execution. The program must process an arbitrary number of grades. How can it determine when to stop the input of grades? How will it know when to calculate and print the class average?

One way to solve this problem is to use a special value called a **sentinel value** (also called a **signal value**, a **dummy value** or a **flag value**) to indicate "end of data entry." The user enters grades until all legitimate grades have been entered. The user then types the sentinel value to indicate that no more grades will be entered. **Sentinel-controlled repetition** is often called **indefinite repetition** because the number of repetitions is *not* known before the loop begins executing.

Clearly, a sentinel value must be chosen that cannot be confused with an acceptable input value. Grades on a quiz are nonnegative integers, so  $-1$  is an acceptable sentinel value for this problem. Thus, a run of the class-average program might process a stream of inputs such as 95, 96, 75, 74, 89 and  $-1$ . The program would then compute and print the class average for the grades 95, 96, 75, 74 and 89; since  $-1$  is the sentinel value, it should *not* enter into the averaging calculation.

### *Developing the Pseudocode Algorithm with Top-Down, Stepwise Refinement: The Top and First Refinement*

We approach this class-average program with a technique called **top-down, stepwise refinement**, which is essential to the development of well-structured programs. We begin with a pseudocode representation of the **top**—a single statement that conveys the overall function of the program:

*Determine the class average for the quiz*

The top is, in effect, a *complete* representation of a program. Unfortunately, the top rarely conveys sufficient detail from which to write a Java program. So we now begin the refinement process. We divide the top into a series of smaller tasks and list these in the order in which they'll be performed. This results in the following **first refinement**:

*Initialize variables*  
*Input, sum and count the quiz grades*  
*Calculate and print the class average*

This refinement uses only the sequence structure—the steps listed should execute in order, one after the other.

#### Software Engineering Observation 4.2

*Each refinement, as well as the top itself, is a complete specification of the algorithm—only the level of detail varies.*

#### Software Engineering Observation 4.3

*Many programs can be divided logically into three phases: an initialization phase that initializes the variables; a processing phase that inputs data values and adjusts program variables accordingly; and a termination phase that calculates and outputs the final results.*

#### *Proceeding to the Second Refinement*

The preceding Software Engineering Observation is often all you need for the first refinement in the top-down process. To proceed to the next level of refinement—that is, the **second refinement**—we commit to specific variables. In this example, we need a running total of the numbers, a count of how many numbers have been processed, a variable to receive the value of each grade as it's input by the user and a variable to hold the calculated average. The pseudocode statement

*Initialize variables*

can be refined as follows:

*Initialize total to zero*  
*Initialize counter to zero*

Only the variables *total* and *counter* need to be initialized before they're used. The variables *average* and *grade* (for the calculated average and the user input, respectively) need not be initialized, because their values will be replaced as they're calculated or input.

The pseudocode statement

*Input, sum and count the quiz grades*

requires a repetition structure (i.e., a loop) that successively inputs each grade. We do not know in advance how many grades are to be processed, so we'll use sentinel-controlled repetition. The user enters grades one at a time. After entering the last grade, the user enters the sentinel value. The program tests for the sentinel value after each grade is input and terminates the loop when the user enters the sentinel value. The second refinement of the preceding pseudocode statement is then

```

    Prompt the user to enter the first grade
    Input the first grade (possibly the sentinel)

    While the user has not yet entered the sentinel
        Add this grade into the running total
        Add one to the grade counter
        Prompt the user to enter the next grade
        Input the next grade (possibly the sentinel)

```

In pseudocode, we do not use braces around the statements that form the body of the *While* structure. We simply indent the statements under the *While* to show that they belong to the *While*. Again, pseudocode is only an informal program development aid.

The pseudocode statement

```

    Calculate and print the class average

```

can be refined as follows:

```

    If the counter is not equal to zero
        Set the average to the total divided by the counter
        Print the average
    else
        Print "No grades were entered"

```

We're careful here to test for the possibility of division by zero—a logic error that, if undetected, would cause the program to fail or produce invalid output. The complete second refinement of the pseudocode for the class-average problem is shown in Fig. 4.8.

#### **Error-Prevention Tip 4.2**

When performing division by an expression whose value could be zero, test for this and handle it (e.g., print an error message) rather than allow the error to occur.

```

1  Initialize total to zero
2  Initialize counter to zero
3
4  Prompt the user to enter the first grade
5  Input the first grade (possibly the sentinel)
6
7  While the user has not yet entered the sentinel
8      Add this grade into the running total
9      Add one to the grade counter
10     Prompt the user to enter the next grade
11     Input the next grade (possibly the sentinel)
12
13    If the counter is not equal to zero
14        Set the average to the total divided by the counter
15        Print the average
16    else
17        Print "No grades were entered"

```

**Fig. 4.8** | Class-average problem pseudocode algorithm with sentinel-controlled repetition.

In Fig. 4.5 and Fig. 4.8, we included blank lines and indentation in the pseudocode to make it more readable. The blank lines separate the algorithms into their phases and set off control statements; the indentation emphasizes the bodies of the control statements.

The pseudocode algorithm in Fig. 4.8 solves the more general class-average problem. This algorithm was developed after two refinements. Sometimes more are needed.

#### Software Engineering Observation 4.4

*Terminate the top-down, stepwise refinement process when you've specified the pseudocode algorithm in sufficient detail for you to convert the pseudocode to Java. Normally, implementing the Java program is then straightforward.*

#### Software Engineering Observation 4.5

*Some programmers do not use program development tools like pseudocode. They feel that their ultimate goal is to solve the problem on a computer and that writing pseudocode merely delays the production of final outputs. Although this may work for simple and familiar problems, it can lead to serious errors and delays in large, complex projects.*

### Implementing Sentinel-Controlled Repetition in Class `GradeBook`

Figure 4.9 shows the Java class `GradeBook` containing method `determineClassAverage` that implements the pseudocode algorithm of Fig. 4.8. Although each grade is an integer, the averaging calculation is likely to produce a number with a decimal point—in other words, a real (i.e., floating-point) number. The type `int` cannot represent such a number, so this class uses type `double` to do so.

```

1 // Fig. 4.9: GradeBook.java
2 // GradeBook class that solves the class-average problem using
3 // sentinel-controlled repetition.
4 import java.util.Scanner; // program uses class Scanner
5
6 public class GradeBook
7 {
8     private String courseName; // name of course this GradeBook represents
9
10    // constructor initializes courseName
11    public GradeBook( String name )
12    {
13        courseName = name; // initializes courseName
14    } // end constructor
15
16    // method to set the course name
17    public void setCourseName( String name )
18    {
19        courseName = name; // store the course name
20    } // end method setCourseName
21
22    // method to retrieve the course name
23    public String getCourseName()
24    {

```

**Fig. 4.9** | `GradeBook` class that solves the class-average problem using sentinel-controlled repetition. (Part I of 3.)

```

25     return courseName;
26 } // end method getCourseName
27
28 // display a welcome message to the GradeBook user
29 public void displayMessage()
30 {
31     // getCourseName gets the name of the course
32     System.out.printf( "Welcome to the grade book for\n%s!\n\n",
33         getCourseName() );
34 } // end method displayMessage
35
36 // determine the average of an arbitrary number of grades
37 public void determineClassAverage()
38 {
39     // create Scanner to obtain input from command window
40     Scanner input = new Scanner( System.in );
41
42     int total; // sum of grades
43     int gradeCounter; // number of grades entered
44     int grade; // grade value
45     double average; // number with decimal point for average
46
47     // initialization phase
48     total = 0; // initialize total
49     gradeCounter = 0; // initialize loop counter
50
51     // processing phase
52     // prompt for input and read grade from user
53     System.out.print( "Enter grade or -1 to quit: " );
54     grade = input.nextInt();
55
56     // loop until sentinel value read from user
57     while ( grade != -1 )
58     {
59         total = total + grade; // add grade to total
60         gradeCounter = gradeCounter + 1; // increment counter
61
62         // prompt for input and read next grade from user
63         System.out.print( "Enter grade or -1 to quit: " );
64         grade = input.nextInt();
65     } // end while
66
67     // termination phase
68     // if user entered at least one grade...
69     if ( gradeCounter != 0 )
70     {
71         // calculate average of all grades entered
72         average = (double) total / gradeCounter;
73
74         // display total and average (with two digits of precision)
75         System.out.printf( "\nTotal of the %d grades entered is %d\n",
76             gradeCounter, total );

```

**Fig. 4.9** | GradeBook class that solves the class-average problem using sentinel-controlled repetition. (Part 2 of 3.)

```
77     System.out.printf( "Class average is %.2f\n", average );
78     } // end if
79     else // no grades were entered, so output appropriate message
80         System.out.println( "No grades were entered" );
81     } // end method determineClassAverage
82 } // end class GradeBook
```

**Fig. 4.9** | GradeBook class that solves the class-average problem using sentinel-controlled repetition. (Part 3 of 3.)

In this example, we see that control statements may be *stacked* on top of one another (in sequence). The `while` statement (lines 57–65) is followed in sequence by an `if...else` statement (lines 69–80). Much of the code in this program is identical to that in Fig. 4.6, so we concentrate on the new concepts.

Line 45 declares `double` variable `average`, which allows us to store the class average as a floating-point number. Line 49 initializes `gradeCounter` to 0, because no grades have been entered yet. Remember that this program uses sentinel-controlled repetition to input the grades. To keep an accurate record of the number of grades entered, the program increments `gradeCounter` only when the user enters a valid grade.

#### *Program Logic for Sentinel-Controlled Repetition vs. Counter-Controlled Repetition*

Compare the program logic for sentinel-controlled repetition in this application with that for counter-controlled repetition in Fig. 4.6. In counter-controlled repetition, each iteration of the `while` statement (e.g., lines 52–58 of Fig. 4.6) reads a value from the user, for the specified number of iterations. In sentinel-controlled repetition, the program reads the first value (lines 53–54 of Fig. 4.9) before reaching the `while`. This value determines whether the program's flow of control should enter the body of the `while`. If the condition of the `while` is false, the user entered the sentinel value, so the body of the `while` does not execute (i.e., no grades were entered). If, on the other hand, the condition is true, the body begins execution, and the loop adds the grade value to the `total` (line 59). Then lines 63–64 in the loop body input the next value from the user. Next, program control reaches the closing right brace of the loop body at line 65, so execution continues with the test of the `while`'s condition (line 57). The condition uses the most recent grade input by the user to determine whether the loop body should execute again. The value of variable `grade` is always input from the user immediately before the program tests the `while` condition. This allows the program to determine whether the value just input is the sentinel value *before* the program processes that value (i.e., adds it to the `total`). If the sentinel value is input, the loop terminates, and the program does not add `-1` to the `total`.

#### **Good Programming Practice 4.3**

*In a sentinel-controlled loop, prompts should remind the user of the sentinel.*

After the loop terminates, the `if...else` statement at lines 69–80 executes. The condition at line 69 determines whether any grades were input. If none were input, the `else` part (lines 79–80) of the `if...else` statement executes and displays the message "No grades were entered" and the method returns control to the calling method.

Notice the `while` statement's block in Fig. 4.9 (lines 58–65). Without the braces, the loop would consider its body to be only the first statement, which adds the grade to the

total. The last three statements in the block would fall outside the loop body, causing the computer to interpret the code incorrectly as follows:

```
while ( grade != -1 )
    total = total + grade; // add grade to total
    gradeCounter = gradeCounter + 1; // increment counter
// prompt for input and read next grade from user
System.out.print( "Enter grade or -1 to quit: " );
grade = input.nextInt();
```

The preceding code would cause an infinite loop in the program if the user did not input the sentinel -1 at line 54 (before the `while` statement).

#### Common Programming Error 4.5

Omitting the braces that delimit a block can lead to logic errors, such as infinite loops. To prevent this problem, some programmers enclose the body of every control statement in braces, even if the body contains only a single statement.

#### Explicitly and Implicitly Converting Between Primitive Types

If at least one grade was entered, line 72 of Fig. 4.9 calculates the average of the grades. Recall from Fig. 4.6 that integer division yields an integer result. Even though variable `average` is declared as a `double` (line 45), the calculation

```
average = total / gradeCounter;
```

loses the fractional part of the quotient *before* the result of the division is assigned to `average`. This occurs because `total` and `gradeCounter` are *both* integers, and integer division yields an integer result. To perform a floating-point calculation with integer values, we must temporarily treat these values as floating-point numbers for use in the calculation. Java provides the **unary cast operator** to accomplish this task. Line 72 uses the **(double)** cast operator—a unary operator—to create a *temporary* floating-point copy of its operand `total` (which appears to the right of the operator). Using a cast operator in this manner is called **explicit conversion** or **type casting**. The value stored in `total` is still an integer.

The calculation now consists of a floating-point value (the temporary `double` version of `total`) divided by the integer `gradeCounter`. Java knows how to evaluate only arithmetic expressions in which the operands' types are *identical*. To ensure that the operands are of the same type, Java performs an operation called **promotion** (or **implicit conversion**) on selected operands. For example, in an expression containing values of the types `int` and `double`, the `int` values are promoted to `double` values for use in the expression. In this example, the value of `gradeCounter` is promoted to type `double`, then the floating-point division is performed and the result of the calculation is assigned to `average`. As long as the `(double)` cast operator is applied to *any* variable in the calculation, the calculation will yield a `double` result. Later in this chapter, we discuss all the primitive types. You'll learn more about the promotion rules in Section 6.7.

#### Common Programming Error 4.6

A cast operator can be used to convert between primitive numeric types, such as `int` and `double`, and between related reference types (as we discuss in Chapter 10, *Object-Oriented Programming: Polymorphism*). Casting to the wrong type may cause compilation errors or runtime errors.

A cast operator is formed by placing parentheses around any type's name. The operator is a **unary operator** (i.e., an operator that takes only one operand). Java also supports unary versions of the plus (+) and minus (-) operators, so you can write expressions like -7 or +5. Cast operators associate from right to left and have the same precedence as other unary operators, such as unary + and unary -. This precedence is one level higher than that of the **multiplicative operators** \*, / and %. (See the operator precedence chart in Appendix A.) We indicate the cast operator with the notation (*type*) in our precedence charts, to indicate that any type name can be used to form a cast operator.

Line 77 displays the class average. In this example, we display the class average rounded to the nearest hundredth. The format specifier %.2f in printf's format control string indicates that variable average's value should be displayed with two digits of precision to the right of the decimal point—indicated by .2 in the format specifier. The three grades entered during the sample execution of class GradeBookTest (Fig. 4.10) total 257, which yields the average 85.666666.... Method printf uses the precision in the format specifier to round the value to the specified number of digits. In this program, the average is rounded to the hundredths position and is displayed as 85.67.

```

1 // Fig. 4.10: GradeBookTest.java
2 // Create GradeBook object and invoke its determineClassAverage method.
3
4 public class GradeBookTest
5 {
6     public static void main( String[] args )
7     {
8         // create GradeBook object myGradeBook and
9         // pass course name to constructor
10        GradeBook myGradeBook = new GradeBook(
11            "CS101 Introduction to Java Programming" );
12
13        myGradeBook.displayMessage(); // display welcome message
14        myGradeBook.determineClassAverage(); // find average of grades
15    } // end main
16 } // end class GradeBookTest

```

```

Welcome to the grade book for
CS101 Introduction to Java Programming!

Enter grade or -1 to quit: 97
Enter grade or -1 to quit: 88
Enter grade or -1 to quit: 72
Enter grade or -1 to quit: -1

Total of the 3 grades entered is 257
Class average is 85.67

```

**Fig. 4.10** | GradeBookTest class creates an object of class GradeBook (Fig. 4.9) and invokes its determineClassAverage method.

## 4.10 Formulating Algorithms: Nested Control Statements

For the next example, we once again formulate an algorithm by using pseudocode and top-down, stepwise refinement, and write a corresponding Java program. We've seen that con-

trol statements can be stacked on top of one another (in sequence). In this case study, we examine the only other structured way control statements can be connected—namely, by **nesting** one control statement within another.

Consider the following problem statement:

*A college offers a course that prepares students for the state licensing exam for real estate brokers. Last year, ten of the students who completed this course took the exam. The college wants to know how well its students did on the exam. You've been asked to write a program to summarize the results. You've been given a list of these 10 students. Next to each name is written a 1 if the student passed the exam or a 2 if the student failed.*

*Your program should analyze the results of the exam as follows:*

- 1. Input each test result (i.e., a 1 or a 2). Display the message "Enter result" on the screen each time the program requests another test result.*
- 2. Count the number of test results of each type.*
- 3. Display a summary of the test results, indicating the number of students who passed and the number who failed.*
- 4. If more than eight students passed the exam, print the message "Bonus to instructor!"*

After reading the problem statement carefully, we make the following observations:

- 1.** The program must process test results for 10 students. A counter-controlled loop can be used, because the number of test results is known in advance.
- 2.** Each test result has a numeric value—either a 1 or a 2. Each time it reads a test result, the program must determine whether it's a 1 or a 2. We test for a 1 in our algorithm. If the number is not a 1, we assume that it's a 2. (Exercise 4.24 considers the consequences of this assumption.)
- 3.** Two counters are used to keep track of the exam results—one to count the number of students who passed the exam and one to count the number who failed.
- 4.** After the program has processed all the results, it must decide whether more than eight students passed the exam.

Let's proceed with top-down, stepwise refinement. We begin with a pseudocode representation of the top:

*Analyze exam results and decide whether a bonus should be paid*

Once again, the top is a *complete* representation of the program, but several refinements are likely to be needed before the pseudocode can evolve naturally into a Java program.

Our first refinement is

*Initialize variables*

*Input the 10 exam results, and count passes and failures*

*Print a summary of the exam results and decide whether a bonus should be paid*

Here, too, even though we have a *complete* representation of the entire program, further refinement is necessary. We now commit to specific variables. Counters are needed to record the passes and failures, a counter will be used to control the looping process and a variable is needed to store the user input. The variable in which the user input will be

stored is *not* initialized at the start of the algorithm, because its value is read from the user during each iteration of the loop.

The pseudocode statement

```
Initialize variables
```

can be refined as follows:

```
Initialize passes to zero
Initialize failures to zero
Initialize student counter to one
```

Notice that only the counters are initialized at the start of the algorithm.

The pseudocode statement

```
Input the 10 exam results, and count passes and failures
```

requires a loop that successively inputs the result of each exam. We know in advance that there are precisely 10 exam results, so counter-controlled looping is appropriate. Inside the loop (i.e., *nested* within the loop), a double-selection structure will determine whether each exam result is a pass or a failure and will increment the appropriate counter. The refinement of the preceding pseudocode statement is then

```
While student counter is less than or equal to 10
  Prompt the user to enter the next exam result
  Input the next exam result
  If the student passed
    Add one to passes
  Else
    Add one to failures
  Add one to student counter
```

We use blank lines to isolate the *If...Else* control structure, which improves readability.

The pseudocode statement

```
Print a summary of the exam results and decide whether a bonus should be paid
```

can be refined as follows:

```
Print the number of passes
Print the number of failures
If more than eight students passed
  Print "Bonus to instructor!"
```

### **Complete Second Refinement of Pseudocode and Conversion to Class Analysis**

The complete second refinement appears in Fig. 4.11. Notice that blank lines are also used to set off the *While* structure for program readability. This pseudocode is now sufficiently refined for conversion to Java.

The Java class that implements the pseudocode algorithm and two sample executions are shown in Fig. 4.12. Lines 13–16 of `main` declare the variables that method `processExamResults` of class `Analysis` uses to process the examination results. Several of these

---

```

1  Initialize passes to zero
2  Initialize failures to zero
3  Initialize student counter to one
4
5  While student counter is less than or equal to 10
6      Prompt the user to enter the next exam result
7      Input the next exam result
8
9      If the student passed
10         Add one to passes
11     Else
12         Add one to failures
13
14     Add one to student counter
15
16 Print the number of passes
17 Print the number of failures
18
19 If more than eight students passed
20     Print "Bonus to instructor!"

```

---

**Fig. 4.11** | Pseudocode for examination-results problem.

declarations use Java's ability to incorporate variable initialization into declarations (`passes` is assigned 0, `failures` 0 and `studentCounter` 1). Looping programs may require initialization at the beginning of each repetition—normally performed by assignment statements rather than in declarations.

#### Error-Prevention Tip 4.3

*Initializing local variables when they're declared helps you avoid any compilation errors that might arise from attempts to use uninitialized variables. While Java does not require that local-variable initializations be incorporated into declarations, it does require that local variables be initialized before their values are used in an expression.*

The `while` statement (lines 19–33) loops 10 times. During each iteration, the loop inputs and processes one exam result. Notice that the `if...else` statement (lines 26–29) for processing each result is nested in the `while` statement. If the `result` is 1, the `if...else` statement increments `passes`; otherwise, it assumes the `result` is 2 and increments `failures`. Line 32 increments `studentCounter` before the loop condition is tested again at line 19. After 10 values have been input, the loop terminates and line 36 displays the number of `passes` and `failures`. The `if` statement at lines 39–40 determines whether more than eight students passed the exam and, if so, outputs the message "Bonus to instructor!".

---

```

1  // Fig. 4.12: Analysis.java
2  // Analysis of examination results using nested control statements.
3  import java.util.Scanner; // class uses class Scanner

```

---

**Fig. 4.12** | Analysis of examination results using nested control statements. (Part I of 3.)

```

4
5 public class Analysis
6 {
7     public static void main( String[] args )
8     {
9         // create Scanner to obtain input from command window
10        Scanner input = new Scanner( System.in );
11
12        // initializing variables in declarations
13        int passes = 0; // number of passes
14        int failures = 0; // number of failures
15        int studentCounter = 1; // student counter
16        int result; // one exam result (obtains value from user)
17
18        // process 10 students using counter-controlled loop
19        while ( studentCounter <= 10 )
20        {
21            // prompt user for input and obtain value from user
22            System.out.print( "Enter result (1 = pass, 2 = fail): " );
23            result = input.nextInt();
24
25            // if...else is nested in the while statement
26            if ( result == 1 ) // if result 1,
27                passes = passes + 1; // increment passes;
28            else // else result is not 1, so
29                failures = failures + 1; // increment failures
30
31            // increment studentCounter so loop eventually terminates
32            studentCounter = studentCounter + 1;
33        } // end while
34
35        // termination phase; prepare and display results
36        System.out.printf( "Passed: %d\nFailed: %d\n", passes, failures );
37
38        // determine whether more than 8 students passed
39        if ( passes > 8 )
40            System.out.println( "Bonus to instructor!" );
41    } // end main
42 } // end class Analysis

```

```

Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 2
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Enter result (1 = pass, 2 = fail): 1
Passed: 9
Failed: 1
Bonus to instructor!

```

Enter result (1 = pass, 2 = fail): 1
Passed: 6
Failed: 4

```

**Fig. 4.12** | Analysis of examination results using nested control statements. (Part 3 of 3.)

Figure 4.12 shows the input and output from two sample executions of the program. During the first, the condition at line 39 of method `main` is `true`—more than eight students passed the exam, so the program outputs a message to bonus the instructor.

This example contains only one class, with method `main` performing all the class's work. In this chapter and in Chapter 3, you've seen examples consisting of two classes—one containing methods that perform useful tasks and one containing method `main`, which creates an object of the other class and calls its methods. Occasionally, when it does not make sense to try to create a reusable class to demonstrate a concept, we'll place the program's statements entirely within the `main` method of a single class.

## 4.11 Compound Assignment Operators

The **compound assignment operators** abbreviate assignment expressions. Statements like

```
variable = variable operator expression;
```

where *operator* is one of the binary operators `+`, `-`, `*`, `/` or `%` (or others we discuss later in the text) can be written in the form

```
variable operator= expression;
```

For example, you can abbreviate the statement

```
c = c + 3;
```

with the **addition compound assignment operator**, `+=`, as

```
c += 3;
```

The `+=` operator adds the value of the expression on its right to the value of the variable on its left and stores the result in the variable on the left of the operator. Thus, the assignment expression `c += 3` adds 3 to `c`. Figure 4.13 shows the arithmetic compound assignment operators, sample expressions using the operators and explanations of what the operators do.

## 4.12 Increment and Decrement Operators

Java provides two unary operators (summarized in Fig. 4.14) for adding 1 to or subtracting 1 from the value of a numeric variable. These are the unary **increment operator**, `++`, and the unary **decrement operator**, `--`. A program can increment by 1 the value of a variable

Assignment operator	Sample expression	Explanation	Assigns
<i>Assume: int c = 3, d = 5, e = 4, f = 6, g = 12;</i>			
+=	c += 7	c = c + 7	10 to c
-=	d -= 4	d = d - 4	1 to d
*=	e *= 5	e = e * 5	20 to e
/=	f /= 3	f = f / 3	2 to f
%=	g %= 9	g = g % 9	3 to g

**Fig. 4.13** | Arithmetic compound assignment operators.

called `c` using the increment operator, `++`, rather than the expression `c = c + 1` or `c += 1`. An increment or decrement operator that's prefixed to (placed before) a variable is referred to as the **prefix increment** or **prefix decrement operator**, respectively. An increment or decrement operator that's postfix to (placed after) a variable is referred to as the **postfix increment** or **postfix decrement operator**, respectively.

Operator	Operator name	Sample expression	Explanation
++	prefix increment	++a	Increment <code>a</code> by 1, then use the new value of <code>a</code> in the expression in which <code>a</code> resides.
++	postfix increment	a++	Use the current value of <code>a</code> in the expression in which <code>a</code> resides, then increment <code>a</code> by 1.
--	prefix decrement	--b	Decrement <code>b</code> by 1, then use the new value of <code>b</code> in the expression in which <code>b</code> resides.
--	postfix decrement	b--	Use the current value of <code>b</code> in the expression in which <code>b</code> resides, then decrement <code>b</code> by 1.

**Fig. 4.14** | Increment and decrement operators.

Using the prefix increment (or decrement) operator to add 1 to (or subtract 1 from) a variable is known as **preincrementing** (or **predecrementing**). This causes the variable to be incremented (decremented) by 1; then the new value of the variable is used in the expression in which it appears. Using the postfix increment (or decrement) operator to add 1 to (or subtract 1 from) a variable is known as **postincrementing** (or **postdecrementing**). This causes the current value of the variable to be used in the expression in which it appears; then the variable's value is incremented (decremented) by 1.

#### Good Programming Practice 4.4

*Unlike binary operators, the unary increment and decrement operators should be placed next to their operands, with no intervening spaces.*

Figure 4.15 demonstrates the difference between the prefix increment and postfix increment versions of the `++` increment operator. The decrement operator (`--`) works similarly.

```

1 // Fig. 4.15: Increment.java
2 // Prefix increment and postfix increment operators.
3
4 public class Increment
5 {
6     public static void main( String[] args )
7     {
8         int c;
9
10        // demonstrate postfix increment operator
11        c = 5; // assign 5 to c
12        System.out.println( c ); // prints 5
13        System.out.println( c++ ); // prints 5 then postincrements
14        System.out.println( c ); // prints 6
15
16        System.out.println(); // skip a line
17
18        // demonstrate prefix increment operator
19        c = 5; // assign 5 to c
20        System.out.println( c ); // prints 5
21        System.out.println( ++c ); // preincrements then prints 6
22        System.out.println( c ); // prints 6
23    } // end main
24 } // end class Increment

```

```

5
5
6

5
6
6

```

**Fig. 4.15** | Preincrementing and postincrementing.

Line 11 initializes the variable `c` to 5, and line 12 outputs `c`'s initial value. Line 13 outputs the value of the expression `c++`. This expression postincrements the variable `c`, so `c`'s original value (5) is output, then `c`'s value is incremented (to 6). Thus, line 13 outputs `c`'s initial value (5) again. Line 14 outputs `c`'s new value (6) to prove that the variable's value was indeed incremented in line 13.

Line 19 resets `c`'s value to 5, and line 20 outputs `c`'s value. Line 21 outputs the value of the expression `++c`. This expression preincrements `c`, so its value is incremented; then the new value (6) is output. Line 22 outputs `c`'s value again to show that the value of `c` is still 6 after line 21 executes.

The arithmetic compound assignment operators and the increment and decrement operators can be used to simplify program statements. For example, the three assignment statements in Fig. 4.12 (lines 27, 29 and 32)

```

passes = passes + 1;
failures = failures + 1;
studentCounter = studentCounter + 1;

```

can be written more concisely with compound assignment operators as

```
passes += 1;
failures += 1;
studentCounter += 1;
```

with prefix increment operators as

```
++passes;
++failures;
++studentCounter;
```

or with postfix increment operators as

```
passes++;
failures++;
studentCounter++;
```

When incrementing or decrementing a variable in a statement by itself, the prefix increment and postfix increment forms have the same effect, and the prefix decrement and postfix decrement forms have the same effect. It's only when a variable appears in the context of a larger expression that preincrementing and postincrementing the variable have different effects (and similarly for predecrementing and postdecrementing).

#### Common Programming Error 4.7

*Attempting to use the increment or decrement operator on an expression other than one to which a value can be assigned is a syntax error. For example, writing `++(x + 1)` is a syntax error, because `(x + 1)` is not a variable.*

Figure 4.16 shows the precedence and associativity of the operators we've introduced. They're shown from top to bottom in decreasing order of precedence. The second column describes the associativity of the operators at each level of precedence. The conditional operator (`?:`); the unary operators increment (`++`), decrement (`--`), plus (`+`) and minus (`-`); the cast operators and the assignment operators `=`, `+=`, `--`, `*=`, `/=` and `%=` associate from right to left. All the other operators in the operator precedence chart in Fig. 4.16 associate from left to right. The third column lists the type of each group of operators.

Operators	Associativity	Type
<code>++</code> <code>--</code>	right to left	unary postfix
<code>++</code> <code>--</code> <code>+</code> <code>-</code> <code>( type )</code>	right to left	unary prefix
<code>*</code> <code>/</code> <code>%</code>	left to right	multiplicative
<code>+</code> <code>-</code>	left to right	additive
<code>&lt;</code> <code>&lt;=</code> <code>&gt;</code> <code>&gt;=</code>	left to right	relational
<code>==</code> <code>!=</code>	left to right	equality
<code>?:</code>	right to left	conditional
<code>=</code> <code>+=</code> <code>--</code> <code>*=</code> <code>/=</code> <code>%=</code>	right to left	assignment

**Fig. 4.16** | Precedence and associativity of the operators discussed so far.

## 4.13 Primitive Types

The table in Appendix D lists the eight primitive types in Java. Like its predecessor languages C and C++, Java requires all variables to have a type. For this reason, Java is referred to as a **strongly typed language**.

In C and C++, programmers frequently have to write separate versions of programs to support different computer platforms, because the primitive types are not guaranteed to be identical from computer to computer. For example, an `int` value on one machine might be represented by 16 bits (2 bytes) of memory, on a second machine by 32 bits (4 bytes) of memory, and on another machine by 64 bits (8 bytes) of memory. In Java, `int` values are always 32 bits (4 bytes).

### Portability Tip 4.1

*The primitive types in Java are portable across all computer platforms that support Java.*

Each type in Appendix D is listed with its size in bits (there are eight bits to a byte) and its range of values. Because the designers of Java want to ensure portability, they use internationally recognized standards for character formats (Unicode; for more information, visit [www.unicode.org](http://www.unicode.org)) and floating-point numbers (IEEE 754; for more information, visit [grouper.ieee.org/groups/754/](http://grouper.ieee.org/groups/754/)).

Recall from Section 3.4 that variables of primitive types declared outside of a method as fields of a class are automatically assigned default values unless explicitly initialized. Instance variables of types `char`, `byte`, `short`, `int`, `long`, `float` and `double` are all given the value 0 by default. Instance variables of type `boolean` are given the value `false` by default. Reference-type instance variables are initialized by default to the value `null`.

## 4.14 (Optional) GUI and Graphics Case Study: Creating Simple Drawings

An appealing feature of Java is its graphics support, which enables you to visually enhance your applications. We now introduce one of Java's graphical capabilities—drawing lines. It also covers the basics of creating a window to display a drawing on the computer screen.

### Java's Coordinate System

To draw in Java, you must understand Java's **coordinate system** (Fig. 4.17), a scheme for identifying points on the screen. By default, the upper-left corner of a GUI component

**Fig. 4.17** | Java coordinate system. Units are measured in pixels.

has the coordinates (0, 0). A coordinate pair is composed of an *x-coordinate* (the **horizontal coordinate**) and a *y-coordinate* (the **vertical coordinate**). The *x-coordinate* is the horizontal location moving from left to right. The *y-coordinate* is the vertical location moving from top to bottom. The *x-axis* describes every horizontal coordinate, and the *y-axis* every vertical coordinate.

Coordinates indicate where graphics should be displayed on a screen. Coordinate units are measured in **pixels**. The term pixel stands for “picture element.” A pixel is a display monitor’s smallest unit of resolution.

### *First Drawing Application*

Our first drawing application simply draws two lines. Class `DrawPanel` (Fig. 4.18) performs the actual drawing, while class `DrawPanelTest` (Fig. 4.19) creates a window to display the drawing. In class `DrawPanel`, the `import` statements in lines 3–4 allow us to use class **Graphics** (from package `java.awt`), which provides various methods for drawing text and shapes onto the screen, and class **JPanel** (from package `javax.swing`), which provides an area on which we can draw.

---

```

1 // Fig. 4.18: DrawPanel.java
2 // Using drawLine to connect the corners of a panel.
3 import java.awt.Graphics;
4 import javax.swing.JPanel;
5
6 public class DrawPanel extends JPanel
7 {
8     // draws an X from the corners of the panel
9     public void paintComponent( Graphics g )
10    {
11        // call paintComponent to ensure the panel displays correctly
12        super.paintComponent( g );
13
14        int width = getWidth(); // total width
15        int height = getHeight(); // total height
16
17        // draw a line from the upper-left to the lower-right
18        g.drawLine( 0, 0, width, height );
19
20        // draw a line from the lower-left to the upper-right
21        g.drawLine( 0, height, width, 0 );
22    } // end method paintComponent
23 } // end class DrawPanel

```

---

**Fig. 4.18** | Using `drawLine` to connect the corners of a panel.

---

```

1 // Fig. 4.19: DrawPanelTest.java
2 // Application to display a DrawPanel.
3 import javax.swing.JFrame;
4
5 public class DrawPanelTest
6 {

```

---

**Fig. 4.19** | Creating `JFrame` to display `DrawPanel`. (Part 1 of 2.)

```

7   public static void main( String[] args )
8   {
9       // create a panel that contains our drawing
10      DrawPanel panel = new DrawPanel();
11
12      // create a new frame to hold the panel
13      JFrame application = new JFrame();
14
15      // set the frame to exit when it is closed
16      application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
17
18      application.add( panel ); // add the panel to the frame
19      application.setSize( 250, 250 ); // set the size of the frame
20      application.setVisible( true ); // make the frame visible
21  } // end main
22 } // end class DrawPanelTest

```

**Fig. 4.19** | Creating JFrame to display DrawPanel. (Part 2 of 2.)

Line 6 uses the keyword **extends** to indicate that class `DrawPanel` is an enhanced type of `JPanel`. The keyword `extends` represents a so-called inheritance relationship in which our new class `DrawPanel` begins with the existing members (data and methods) from class `JPanel`. The class from which `DrawPanel` **inherits**, `JPanel`, appears to the right of keyword `extends`. In this inheritance relationship, `JPanel` is called the **superclass** and `DrawPanel` is called the **subclass**. This results in a `DrawPanel` class that has the attributes (data) and behaviors (methods) of class `JPanel` as well as the new features we're adding in our `DrawPanel` class declaration—specifically, the ability to draw two lines along the diagonals of the panel. Inheritance is explained in detail in Chapter 9. For now, you should mimic our `DrawPanel` class when creating your own graphics programs.

### *Method `paintComponent`*

Every `JPanel`, including our `DrawPanel`, has a **paintComponent** method (lines 9–22), which the system automatically calls every time it needs to display the `JPanel`. Method `paintComponent` must be declared as shown in line 9—otherwise, the system will not call it. This method is called when a `JPanel` is first displayed on the screen, when it's covered then uncovered by a window on the screen and when the window in which it appears is resized. Method `paintComponent` requires one argument, a `Graphics` object, that's provided by the system when it calls `paintComponent`.

The first statement in every `paintComponent` method you create should always be

```
super.paintComponent( g );
```

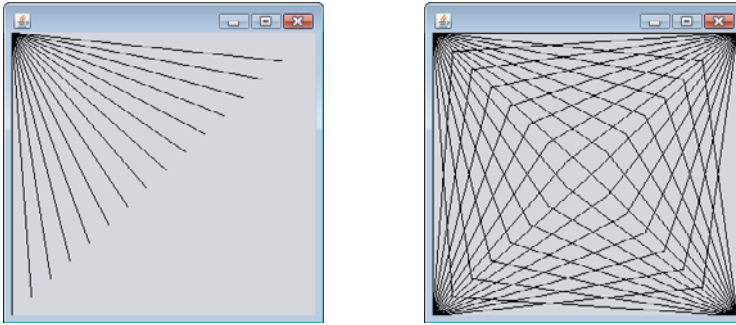

which ensures that the panel is properly rendered before we begin drawing on it. Next, lines 14–15 call methods that class `DrawPanel` inherits from `JPanel`. Because `DrawPanel` extends `JPanel`, `DrawPanel` can use any public methods of `JPanel`. Methods `getWidth` and `getHeight` return the `JPanel`'s width and height, respectively. Lines 14–15 store these values in the local variables `width` and `height`. Finally, lines 18 and 21 use the `Graphics` variable `g` to call method `drawLine` to draw the two lines. Method `drawLine` draws a line between two points represented by its four arguments. The first two arguments are the  $x$ - and  $y$ -coordinates for one endpoint, and the last two arguments are the coordinates for the other endpoint. If you resize the window, the lines will scale accordingly, because the arguments are based on the width and height of the panel. Resizing the window in this application causes the system to call `paintComponent` to redraw the `DrawPanel`'s contents.

### *Class DrawPanelTest*

To display the `DrawPanel` on the screen, you must place it in a window. You create a window with an object of class `JFrame`. In `DrawPanelTest.java` (Fig. 4.19), line 3 imports class `JFrame` from package `javax.swing`. Line 10 in `main` creates a `DrawPanel` object, which contains our drawing, and line 13 creates a new `JFrame` that can hold and display our panel. Line 16 calls `JFrame` method `setDefaultCloseOperation` with the argument `JFrame.EXIT_ON_CLOSE` to indicate that the application should terminate when the user closes the window. Line 18 uses class `JFrame`'s `add` method to attach the `DrawPanel` to the `JFrame`. Line 19 sets the size of the `JFrame`. Method `setSize` takes two parameters that represent the width and height of the `JFrame`, respectively. Finally, line 20 displays the `JFrame` by calling its `setVisible` method with the argument `true`. When the `JFrame` is displayed, the `DrawPanel`'s `paintComponent` method (lines 9–22 of Fig. 4.18) is implicitly called, and the two lines are drawn (see the sample outputs in Fig. 4.19). Try resizing the window to see that the lines always draw based on the window's current width and height.

### *GUI and Graphics Case Study Exercises*

- 4.1** Using loops and control statements to draw lines can lead to many interesting designs.
- Create the design in the left screen capture of Fig. 4.20. This design draws lines from the top-left corner, fanning them out until they cover the upper-left half of the panel. One approach is to divide the width and height into an equal number of steps (we found 15 steps worked well). The first endpoint of a line will always be in the top-left corner (0, 0). The second endpoint can be found by starting at the bottom-left corner and moving up one vertical step and right one horizontal step. Draw a line between the two endpoints. Continue moving up and to the right one step to find each successive endpoint. The figure should scale accordingly as you resize the window.
  - Modify part (a) to have lines fan out from all four corners, as shown in the right screen capture of Fig. 4.20. Lines from opposite corners should intersect along the middle.
- 4.2** Figure 4.21 displays two additional designs created using `while` loops and `drawLine`.
- Create the design in the left screen capture of Fig. 4.21. Begin by dividing each edge into an equal number of increments (we chose 15 again). The first line starts in the top-left corner and ends one step right on the bottom edge. For each successive line, move down one increment on the left edge and right one increment on the bottom edge. Continue drawing lines until you reach the bottom-right corner. The figure should scale as you resize the window so that the endpoints always touch the edges.
  - Modify your answer in part (a) to mirror the design in all four corners, as shown in the right screen capture of Fig. 4.21.

**Fig. 4.20** | Lines fanning from a corner.

**Fig. 4.21** | Line art with loops and drawLine.

## 4.15 Wrap-Up

This chapter presented basic problem solving for building classes and developing methods for these classes. We demonstrated how to construct an algorithm (i.e., an approach to solving a problem), then how to refine the algorithm through several phases of pseudocode development, resulting in Java code that can be executed as part of a method. The chapter showed how to use top-down, stepwise refinement to plan out the specific actions that a method must perform and the order in which the method must perform these actions.

Only three types of control structures—sequence, selection and repetition—are needed to develop any problem-solving algorithm. Specifically, this chapter demonstrated the `if` single-selection statement, the `if...else` double-selection statement and the `while` repetition statement. These are some of the building blocks used to construct solutions to many problems. We used control-statement stacking to total and compute the average of a set of student grades with counter- and sentinel-controlled repetition, and we used control-statement nesting to analyze and make decisions based on a set of exam results. We introduced Java's compound assignment operators and its increment and decrement operators. Finally, we discussed Java's primitive types. In Chapter 5, we continue our discussion of control statements, introducing the `for`, `do...while` and `switch` statements.

## Summary

### Section 4.1 Introduction

- Before writing a program to solve a problem, you must have a thorough understanding of the problem and a carefully planned approach to solving it. You must also understand the building blocks that are available and employ proven program-construction techniques.

### Section 4.2 Algorithms

- Any computing problem can be solved by executing a series of actions (p. 103) in a specific order.
- A procedure for solving a problem in terms of the actions to execute and the order in which they execute is called an algorithm (p. 103).
- Specifying the order in which statements execute in a program is called program control (p. 104).

### Section 4.3 Pseudocode

- Pseudocode (p. 104) is an informal language that helps you develop algorithms without having to worry about the strict details of Java language syntax.
- Pseudocode is similar to everyday English—it's convenient and user friendly, but it's not an actual computer programming language.
- Pseudocode helps you “think out” a program before attempting to write it in a programming language, such as Java.
- Carefully prepared pseudocode can easily be converted to a corresponding Java program.

### Section 4.4 Control Structures

- Normally, statements in a program are executed one after the other in the order in which they're written. This process is called sequential execution (p. 104).
- Various Java statements enable you to specify that the next statement to execute is not necessarily the next one in sequence. This is called transfer of control (p. 104).
- Bohm and Jacopini demonstrated that all programs could be written in terms of only three control structures (p. 105)—the sequence structure, the selection structure and the repetition structure.
- The term “control structures” comes from the field of computer science. The *Java Language Specification* refers to “control structures” as “control statements” (p. 104).
- The sequence structure is built into Java. Unless directed otherwise, the computer executes Java statements one after the other in the order in which they're written—that is, in sequence.
- Anywhere a single action may be placed, several actions may be placed in sequence.
- Activity diagrams (p. 105) are part of the UML. An activity diagram models the workflow (p. 105; also called the activity) of a portion of a software system.
- Activity diagrams are composed of symbols (p. 105)—such as action-state symbols, diamonds and small circles—that are connected by transition arrows, which represent the flow of the activity.
- Action states (p. 105) contain action expressions that specify particular actions to perform.
- The arrows in an activity diagram represent transitions, which indicate the order in which the actions represented by the action states occur.
- The solid circle located at the top of an activity diagram represents the activity's initial state (p. 105)—the beginning of the workflow before the program performs the modeled actions.
- The solid circle surrounded by a hollow circle that appears at the bottom of the diagram represents the final state (p. 106)—the end of the workflow after the program performs its actions.
- Rectangles with their upper-right corners folded over are UML notes (p. 106)—explanatory remarks that describe the purpose of symbols in the diagram.

- Java has three types of selection statements (p. 106).
- The `if` single-selection statement (p. 106) selects or ignores one or more actions.
- The `if...else` double-selection statement selects between two actions or groups of actions.
- The `switch` statement is called a multiple-selection statement (p. 106) because it selects among many different actions or groups of actions.
- Java provides the `while`, `do...while` and `for` repetition (looping) statements that enable programs to perform statements repeatedly as long as a loop-continuation condition remains true.
- The `while` and `for` statements perform the action(s) in their bodies zero or more times—if the loop-continuation condition (p. 106) is initially false, the action(s) will not execute. The `do...while` statement performs the action(s) in its body one or more times.
- The words `if`, `else`, `switch`, `while`, `do` and `for` are Java keywords. Keywords cannot be used as identifiers, such as variable names.
- Every program is formed by combining as many sequence, selection and repetition statements (p. 106) as is appropriate for the algorithm the program implements.
- Single-entry/single-exit control statements (p. 106) are attached to one another by connecting the exit point of one to the entry point of the next. This is known as control-statement stacking.
- A control statement may also be nested (p. 106) inside another control statement.

#### *Section 4.5 if Single-Selection Statement*

- Programs use selection statements to choose among alternative courses of action.
- The single-selection `if` statement's activity diagram contains the diamond symbol, which indicates that a decision is to be made. The workflow follows a path determined by the symbol's associated guard conditions (p. 107). If a guard condition is true, the workflow enters the action state to which the corresponding transition arrow points.
- The `if` statement is a single-entry/single-exit control statement.

#### *Section 4.6 if...else Double-Selection Statement*

- The `if` single-selection statement performs an indicated action only when the condition is true.
- The `if...else` double-selection (p. 106) statement performs one action when the condition is true and a different action when the condition is false.
- The conditional operator (p. 108; `?:`) is Java's only ternary operator—it takes three operands. Together, the operands and the `?:` symbol form a conditional expression (p. 108).
- A program can test multiple cases with nested `if...else` statements (p. 109).
- The Java compiler associates an `else` with the immediately preceding `if` unless told to do otherwise by the placement of braces.
- The `if` statement expects one statement in its body. To include several statements in the body of an `if` (or the body of an `else` for an `if...else` statement), enclose the statements in braces.
- A block (p. 111) of statements can be placed anywhere that a single statement can be placed.
- A logic error (p. 111) has its effect at execution time. A fatal logic error (p. 111) causes a program to fail and terminate prematurely. A nonfatal logic error (p. 111) allows a program to continue executing, but causes the program to produce incorrect results.
- Just as a block can be placed anywhere a single statement can be placed, you can also use an empty statement, represented by placing a semicolon (`;`) where a statement would normally be.

#### *Section 4.7 while Repetition Statement*

- The `while` repetition statement (p. 112) allows you to specify that a program should repeat an action while some condition remains true.

- The UML’s merge (p. 112) symbol joins two flows of activity into one.
- The decision and merge symbols can be distinguished by the number of “incoming” and “outgoing” transition arrows. A decision symbol has (p. 107) one transition arrow pointing to the diamond and two or more transition arrows pointing out from the diamond to indicate possible transitions from that point. Each transition arrow pointing out of a decision symbol has a guard condition. A merge symbol has two or more transition arrows pointing to the diamond and only one transition arrow pointing from the diamond, to indicate multiple activity flows merging to continue the activity. None of the transition arrows associated with a merge symbol has a guard condition.

#### *Section 4.8 Formulating Algorithms: Counter-Controlled Repetition*

- Counter-controlled repetition (p. 113) uses a variable called a counter (or control variable) to control the number of times a set of statements execute.
- Counter-controlled repetition is often called definite repetition (p. 113), because the number of repetitions is known before the loop begins executing.
- A total (p. 114) is a variable used to accumulate the sum of several values. Variables used to store totals are normally initialized to zero before being used in a program.
- A local variable’s declaration must appear before the variable is used in that method. A local variable cannot be accessed outside the method in which it’s declared.
- Dividing two integers results in integer division (p. 118)—the calculation’s fractional part is truncated.

#### *Section 4.9 Formulating Algorithms: Sentinel-Controlled Repetition*

- In sentinel-controlled repetition (p. 118), a special value called a sentinel value (also called a signal value, a dummy value or a flag value) is used to indicate “end of data entry.”
- A sentinel value must be chosen that cannot be confused with an acceptable input value.
- Top-down, stepwise refinement (p. 118) is essential to the development of well-structured programs.
- Division by zero is a logic error.
- To perform a floating-point calculation with integer values, cast (p. 124) one of the integers to type `double`.
- Java knows how to evaluate only arithmetic expressions in which the operands’ types are identical. To ensure this, Java performs an operation called promotion (p. 124) on selected operands.
- The unary cast operator (p. 124) is formed by placing parentheses around the name of a type.

#### *Section 4.11 Compound Assignment Operators*

- The compound assignment operators (p. 130) abbreviate assignment expressions. Statements of the form

*variable* = *variable* *operator* *expression*;

where *operator* is one of the binary operators +, -, \*, / or %, can be written in the form

*variable* *operator* = *expression*;

- The += operator adds the value of the expression on the right of the operator to the value of the variable on the left of the operator and stores the result in the variable on the left of the operator.

#### *Section 4.12 Increment and Decrement Operators*

- The unary increment operator, ++, and the unary decrement operator, --, add 1 to or subtract 1 from the value of a numeric variable (p. 130).

- An increment or decrement operator that's prefixed (p. 131) to a variable is the prefix increment or prefix decrement operator, respectively. An increment or decrement operator that's postfix (p. 131) to a variable is the postfix increment or postfix decrement operator, respectively.
- Using the prefix increment or decrement operator to add or subtract 1 is known as preincrementing or predecrementing, respectively.
- Preincrementing or predecrementing a variable causes the variable to be incremented or decremented by 1; then the new value of the variable is used in the expression in which it appears.
- Using the postfix increment or decrement operator to add or subtract 1 is known as postincrementing or postdecrementing, respectively.
- Postincrementing or postdecrementing the variable causes its value to be used in the expression in which it appears; then the variable's value is incremented or decremented by 1.
- When incrementing or decrementing a variable in a statement by itself, the prefix and postfix increment have the same effect, and the prefix and postfix decrement have the same effect.

### Section 4.13 Primitive Types

- Java requires all variables to have a type. Thus, Java is referred to as a strongly typed language (p. 134).
- Java uses Unicode characters and IEEE 754 floating-point numbers.

## Self-Review Exercises

- 4.1** Fill in the blanks in each of the following statements:
- All programs can be written in terms of three types of control structures: \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - The \_\_\_\_\_ statement is used to execute one action when a condition is true and another when that condition is false.
  - Repeating a set of instructions a specific number of times is called \_\_\_\_\_ repetition.
  - When it's not known in advance how many times a set of statements will be repeated, a(n) \_\_\_\_\_ value can be used to terminate the repetition.
  - The \_\_\_\_\_ structure is built into Java; by default, statements execute in the order they appear.
  - Instance variables of types `char`, `byte`, `short`, `int`, `long`, `float` and `double` are all given the value \_\_\_\_\_ by default.
  - Java is a(n) \_\_\_\_\_ language; it requires all variables to have a type.
  - If the increment operator is \_\_\_\_\_ to a variable, first the variable is incremented by 1, then its new value is used in the expression.
- 4.2** State whether each of the following is *true* or *false*. If *false*, explain why.
- An algorithm is a procedure for solving a problem in terms of the actions to execute and the order in which they execute.
  - A set of statements contained within a pair of parentheses is called a block.
  - A selection statement specifies that an action is to be repeated while some condition remains true.
  - A nested control statement appears in the body of another control statement.
  - Java provides the arithmetic compound assignment operators `+=`, `-=`, `*=`, `/=` and `%=` for abbreviating assignment expressions.
  - The primitive types (`boolean`, `char`, `byte`, `short`, `int`, `long`, `float` and `double`) are portable across only Windows platforms.
  - Specifying the order in which statements execute in a program is called program control.
  - The unary cast operator (`double`) creates a temporary integer copy of its operand.

- i) Instance variables of type `boolean` are given the value `true` by default.
- j) Pseudocode helps you think out a program before attempting to write it in a programming language.

**4.3** Write four different Java statements that each add 1 to integer variable `x`.

**4.4** Write Java statements to accomplish each of the following tasks:

- a) Use one statement to assign the sum of `x` and `y` to `z`, then increment `x` by 1.
- b) Test whether variable `count` is greater than 10. If it is, print "Count is greater than 10".
- c) Use one statement to decrement the variable `x` by 1, then subtract it from variable `total` and store the result in variable `total`.
- d) Calculate the remainder after `q` is divided by `divisor`, and assign the result to `q`. Write this statement in two different ways.

**4.5** Write a Java statement to accomplish each of the following tasks:

- a) Declare variables `sum` and `x` to be of type `int`.
- b) Assign 1 to variable `x`.
- c) Assign 0 to variable `sum`.
- d) Add variable `x` to variable `sum`, and assign the result to variable `sum`.
- e) Print "The sum is: ", followed by the value of variable `sum`.

**4.6** Combine the statements that you wrote in Exercise 4.5 into a Java application that calculates and prints the sum of the integers from 1 to 10. Use a `while` statement to loop through the calculation and increment statements. The loop should terminate when the value of `x` becomes 11.

**4.7** Determine the value of the variables in the statement `product *= x++`; after the calculation is performed. Assume that all variables are type `int` and initially have the value 5.

**4.8** Identify and correct the errors in each of the following sets of code:

- a) 

```
while ( c <= 5 )
{
    product *= c;
    ++c;
}
```
- b) 

```
if ( gender == 1 )
    System.out.println( "Woman" );
else;
    System.out.println( "Man" );
```

**4.9** What is wrong with the following `while` statement?

```
while ( z >= 0 )
    sum += z;
```

## Answers to Self-Review Exercises

**4.1** a) sequence, selection, repetition. b) `if...else`. c) counter-controlled (or definite). d) sentinel, signal, flag or dummy. e) sequence. f) 0 (zero). g) strongly typed. h) prefixed.

**4.2** a) True. b) False. A set of statements contained within a pair of braces (`{` and `}`) is called a block. c) False. A repetition statement specifies that an action is to be repeated while some condition remains true. d) True. e) True. f) False. The primitive types (`boolean`, `char`, `byte`, `short`, `int`, `long`, `float` and `double`) are portable across all computer platforms that support Java. g) True. h) False. The unary cast operator (`double`) creates a temporary floating-point copy of its operand. i) False. Instance variables of type `boolean` are given the value `false` by default. j) True.

**4.3**

```
x = x + 1;
x += 1;
++x;
x++;
```

4.4 a) `z = x++ + y;`  
 b) `if ( count > 10 )`  
     `System.out.println( "Count is greater than 10" );`  
 c) `total -= --x;`  
 d) `q %= divisor;`  
     `q = q % divisor;`

4.5 a) `int sum;`  
     `int x;`  
 b) `x = 1;`  
 c) `sum = 0;`  
 d) `sum += x; or sum = sum + x;`  
 e) `System.out.printf( "The sum is: %d\n", sum );`

4.6 The program is as follows:

```

1 // Exercise 4.6: Calculate.java
2 // Calculate the sum of the integers from 1 to 10
3 public class Calculate
4 {
5     public static void main( String[] args )
6     {
7         int sum;
8         int x;
9
10        x = 1; // initialize x to 1 for counting
11        sum = 0; // initialize sum to 0 for totaling
12
13        while ( x <= 10 ) // while x is less than or equal to 10
14        {
15            sum += x; // add x to sum
16            ++x; // increment x
17        } // end while
18
19        System.out.printf( "The sum is: %d\n", sum );
20    } // end main
21 } // end class Calculate

```

The sum is: 55

4.7 product = 25, x = 6

4.8 a) Error: The closing right brace of the `while` statement's body is missing.  
 Correction: Add a closing right brace after the statement `++c;`.  
 b) Error: The semicolon after `else` results in a logic error. The second output statement will always be executed.  
 Correction: Remove the semicolon after `else`.

4.9 The value of the variable `z` is never changed in the `while` statement. Therefore, if the loop-continuation condition (`z >= 0`) is true, an infinite loop is created. To prevent an infinite loop from occurring, `z` must be decremented so that it eventually becomes less than 0.

## Exercises

4.10 Compare and contrast the `if` single-selection statement and the `while` repetition statement. How are these two statements similar? How are they different?

**4.11** Explain what happens when a Java program attempts to divide one integer by another. What happens to the fractional part of the calculation? How can you avoid that outcome?

**4.12** Describe the two ways in which control statements can be combined.

**4.13** What type of repetition would be appropriate for calculating the sum of the first 100 positive integers? What type would be appropriate for calculating the sum of an arbitrary number of positive integers? Briefly describe how each of these tasks could be performed.

**4.14** What is the difference between preincrementing and postincrementing a variable?

**4.15** Identify and correct the errors in each of the following pieces of code. [*Note:* There may be more than one error in each piece of code.]

- a) `if ( age >= 65 );`  
     `System.out.println( "Age is greater than or equal to 65" );`  
     `else`  
     `System.out.println( "Age is less than 65" );`
- b) `int x = 1, total;`  
     `while ( x <= 10 )`  
     {  
         `total += x;`  
         `++x;`  
     }
- c) `while ( x <= 100 )`  
     `total += x;`  
     `++x;`
- d) `while ( y > 0 )`  
     {  
         `System.out.println( y );`  
         `++y;`  
     }

**4.16** What does the following program print?

---

```

1 // Exercise 4.16: Mystery.java
2 public class Mystery
3 {
4     public static void main( String[] args )
5     {
6         int y;
7         int x = 1;
8         int total = 0;
9
10        while ( x <= 10 )
11        {
12            y = x * x;
13            System.out.println( y );
14            total += y;
15            ++x;
16        } // end while
17
18        System.out.printf( "Total is %d\n", total );
19    } // end main
20 } // end class Mystery

```

---

For Exercise 4.17 through Exercise 4.20, perform each of the following steps:

- Read the problem statement.
- Formulate the algorithm using pseudocode and top-down, stepwise refinement.

- c) Write a Java program.
- d) Test, debug and execute the Java program.
- e) Process three complete sets of data.

**4.17** (*Gas Mileage*) Drivers are concerned with the mileage their automobiles get. One driver has kept track of several trips by recording the miles driven and gallons used for each tankful. Develop a Java application that will input the miles driven and gallons used (both as integers) for each trip. The program should calculate and display the miles per gallon obtained for each trip and print the combined miles per gallon obtained for all trips up to this point. All averaging calculations should produce floating-point results. Use class `Scanner` and sentinel-controlled repetition to obtain the data from the user.

**4.18** (*Credit Limit Calculator*) Develop a Java application that determines whether any of several department-store customers has exceeded the credit limit on a charge account. For each customer, the following facts are available:

- a) account number
- b) balance at the beginning of the month
- c) total of all items charged by the customer this month
- d) total of all credits applied to the customer's account this month
- e) allowed credit limit.

The program should input all these facts as integers, calculate the new balance ( $= \textit{beginning balance} + \textit{charges} - \textit{credits}$ ), display the new balance and determine whether the new balance exceeds the customer's credit limit. For those customers whose credit limit is exceeded, the program should display the message "Credit limit exceeded".

**4.19** (*Sales Commission Calculator*) A large company pays its salespeople on a commission basis. The salespeople receive \$200 per week plus 9% of their gross sales for that week. For example, a salesperson who sells \$5000 worth of merchandise in a week receives \$200 plus 9% of \$5000, or a total of \$650. You've been supplied with a list of the items sold by each salesperson. The values of these items are as follows:

Item	Value
1	239.99
2	129.75
3	99.95
4	350.89

Develop a Java application that inputs one salesperson's items sold for last week and calculates and displays that salesperson's earnings. There's no limit to the number of items that can be sold.

**4.20** (*Salary Calculator*) Develop a Java application that determines the gross pay for each of three employees. The company pays straight time for the first 40 hours worked by each employee and time and a half for all hours worked in excess of 40. You're given a list of the employees, their number of hours worked last week and their hourly rates. Your program should input this information for each employee, then determine and display the employee's gross pay. Use class `Scanner` to input the data.

**4.21** (*Find the Largest Number*) The process of finding the largest value is used frequently in computer applications. For example, a program that determines the winner of a sales contest would input the number of units sold by each salesperson. The salesperson who sells the most units wins the contest. Write a pseudocode program, then a Java application that inputs a series of 10 integers and determines and prints the largest integer. Your program should use at least the following three variables:

- a) counter: A counter to count to 10 (i.e., to keep track of how many numbers have been input and to determine when all 10 numbers have been processed).
- b) number: The integer most recently input by the user.
- c) largest: The largest number found so far.

**4.22 (Tabular Output)** Write a Java application that uses looping to print the following table of values:

N	10*N	100*N	1000*N
1	10	100	1000
2	20	200	2000
3	30	300	3000
4	40	400	4000
5	50	500	5000

**4.23 (Find the Two Largest Numbers)** Using an approach similar to that for Exercise 4.21, find the *two* largest values of the 10 values entered. [Note: You may input each number only once.]

**4.24 (Validating User Input)** Modify the program in Fig. 4.12 to validate its inputs. For any input, if the value entered is other than 1 or 2, keep looping until the user enters a correct value.

**4.25** What does the following program print?

```

1 // Exercise 4.25: Mystery2.java
2 public class Mystery2
3 {
4     public static void main( String[] args )
5     {
6         int count = 1;
7
8         while ( count <= 10 )
9         {
10            System.out.println( count % 2 == 1 ? "****" : "+++++++" );
11            ++count;
12        } // end while
13    } // end main
14 } // end class Mystery2

```

**4.26** What does the following program print?

```

1 // Exercise 4.26: Mystery3.java
2 public class Mystery3
3 {
4     public static void main( String[] args )
5     {
6         int row = 10;
7         int column;
8
9         while ( row >= 1 )
10        {
11            column = 1;
12
13            while ( column <= 10 )
14            {
15                System.out.print( row % 2 == 1 ? "<" : ">" );
16                ++column;
17            } // end while
18
19            --row;
20            System.out.println();
21        } // end while
22    } // end main
23 } // end class Mystery3

```

**4.27** (*Dangling-else Problem*) Determine the output for each of the given sets of code when  $x$  is 9 and  $y$  is 11 and when  $x$  is 11 and  $y$  is 9. The compiler ignores the indentation in a Java program. Also, the Java compiler always associates an `else` with the immediately preceding `if` unless told to do otherwise by the placement of braces (`{}`). On first glance, you may not be sure which `if` a particular `else` matches—this situation is referred to as the “dangling-else problem.” We’ve eliminated the indentation from the following code to make the problem more challenging. [*Hint*: Apply the indentation conventions you’ve learned.]

- a) 

```
if ( x < 10 )
    if ( y > 10 )
        System.out.println( "*****" );
    else
        System.out.println( "#####" );
        System.out.println( "$$$$" );
```
- b) 

```
if ( x < 10 )
{
    if ( y > 10 )
        System.out.println( "*****" );
}
else
{
    System.out.println( "#####" );
    System.out.println( "$$$$" );
}
```

**4.28** (*Another Dangling-else Problem*) Modify the given code to produce the output shown in each part of the problem. Use proper indentation techniques. Make no changes other than inserting braces and changing the indentation of the code. The compiler ignores indentation in a Java program. We’ve eliminated the indentation from the given code to make the problem more challenging. [*Note*: It’s possible that no modification is necessary for some of the parts.]

```
if ( y == 8 )
if ( x == 5 )
    System.out.println( "#####" );
else
    System.out.println( "#####" );
    System.out.println( "$$$$" );
    System.out.println( "#####" );
```

- a) Assuming that  $x = 5$  and  $y = 8$ , the following output is produced:

```
#####
$$$$$
#####" ;
```

- b) Assuming that  $x = 5$  and  $y = 8$ , the following output is produced:

```
#####" ;
```

- c) Assuming that  $x = 5$  and  $y = 8$ , the following output is produced:

```
#####" ;
```

- d) Assuming that  $x = 5$  and  $y = 7$ , the following output is produced. [*Note*: The last three output statements after the `else` are all part of a block.]

```
#####
$$$$$
#####" ;
```

**4.29** (*Square of Asterisks*) Write an application that prompts the user to enter the size of the side of a square, then displays a hollow square of that size made of asterisks. Your program should work for squares of all side lengths between 1 and 20.

**4.30** (*Palindromes*) A palindrome is a sequence of characters that reads the same backward as forward. For example, each of the following five-digit integers is a palindrome: 12321, 55555, 45554 and 11611. Write an application that reads in a five-digit integer and determines whether it's a palindrome. If the number is not five digits long, display an error message and allow the user to enter a new value.

**4.31** (*Printing the Decimal Equivalent of a Binary Number*) Write an application that inputs an integer containing only 0s and 1s (i.e., a binary integer) and prints its decimal equivalent. [*Hint*: Use the remainder and division operators to pick off the binary number's digits one at a time, from right to left. In the decimal number system, the rightmost digit has a positional value of 1 and the next digit to the left a positional value of 10, then 100, then 1000, and so on. The decimal number 234 can be interpreted as  $4 * 1 + 3 * 10 + 2 * 100$ . In the binary number system, the rightmost digit has a positional value of 1, the next digit to the left a positional value of 2, then 4, then 8, and so on. The decimal equivalent of binary 1101 is  $1 * 1 + 0 * 2 + 1 * 4 + 1 * 8$ , or  $1 + 0 + 4 + 8$  or, 13.]

**4.32** (*Checkerboard Pattern of Asterisks*) Write an application that uses only the output statements

```
System.out.print( "* " );
System.out.print( " " );
System.out.println();
```

to display the checkerboard pattern that follows. A `System.out.println` method call with no arguments causes the program to output a single newline character. [*Hint*: Repetition statements are required.]

```
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
 * * * * *
* * * * *
```

**4.33** (*Multiples of 2 with an Infinite Loop*) Write an application that keeps displaying in the command window the multiples of the integer 2—namely, 2, 4, 8, 16, 32, 64, and so on. Your loop should not terminate (i.e., it should create an infinite loop). What happens when you run this program?

**4.34** (*What's Wrong with This Code?*) What is wrong with the following statement? Provide the correct statement to add one to the sum of `x` and `y`.

```
System.out.println( ++(x + y) );
```

**4.35** (*Sides of a Triangle*) Write an application that reads three nonzero values entered by the user and determines and prints whether they could represent the sides of a triangle.

**4.36** (*Sides of a Right Triangle*) Write an application that reads three nonzero integers and determines and prints whether they could represent the sides of a right triangle.

**4.37** (*Factorial*) The factorial of a nonnegative integer  $n$  is written as  $n!$  (pronounced “ $n$  factorial”) and is defined as follows:

$$n! = n \cdot (n - 1) \cdot (n - 2) \cdot \dots \cdot 1 \quad (\text{for values of } n \text{ greater than or equal to } 1)$$

and

$$n! = 1 \quad (\text{for } n = 0)$$

For example,  $5! = 5 \cdot 4 \cdot 3 \cdot 2 \cdot 1$ , which is 120.

- Write an application that reads a nonnegative integer and computes and prints its factorial.
- Write an application that estimates the value of the mathematical constant  $e$  by using the following formula. Allow the user to enter the number of terms to calculate.

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \dots$$

- Write an application that computes the value of  $e^x$  by using the following formula. Allow the user to enter the number of terms to calculate.

$$e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$

## Making a Difference

**4.38** (*Enforcing Privacy with Cryptography*) The explosive growth of Internet communications and data storage on Internet-connected computers has greatly increased privacy concerns. The field of cryptography is concerned with coding data to make it difficult (and hopefully—with the most advanced schemes—impossible) for unauthorized users to read. In this exercise you'll investigate a simple scheme for encrypting and decrypting data. A company that wants to send data over the Internet has asked you to write a program that will encrypt it so that it may be transmitted more securely. All the data is transmitted as four-digit integers. Your application should read a four-digit integer entered by the user and encrypt it as follows: Replace each digit with the result of adding 7 to the digit and getting the remainder after dividing the new value by 10. Then swap the first digit with the third, and swap the second digit with the fourth. Then print the encrypted integer. Write a separate application that inputs an encrypted four-digit integer and decrypts it (by reversing the encryption scheme) to form the original number. [*Optional reading project:* Research “public key cryptography” in general and the PGP (Pretty Good Privacy) specific public key scheme. You may also want to investigate the RSA scheme, which is widely used in industrial-strength applications.]

**4.39** (*World Population Growth*) World population has grown considerably over the centuries. Continued growth could eventually challenge the limits of breathable air, drinkable water, arable cropland and other limited resources. There's evidence that growth has been slowing in recent years and that world population could peak some time this century, then start to decline.

For this exercise, research world population growth issues online. *Be sure to investigate various viewpoints.* Get estimates for the current world population and its growth rate (the percentage by which it's likely to increase this year). Write a program that calculates world population growth each year for the next 75 years, *using the simplifying assumption that the current growth rate will stay constant.* Print the results in a table. The first column should display the year from year 1 to year 75. The second column should display the anticipated world population at the end of that year. The third column should display the numerical increase in the world population that would occur that year. Using your results, determine the year in which the population would be double what it is today, if this year's growth rate were to persist.

## Control Statements: Part 2

# 5

*The wheel is come full circle.*

—William Shakespeare

—Robert Frost

*All the evolution we know of  
proceeds from the vague to the  
definite.*

—Charles Sanders Peirce

### Objectives

In this chapter you'll learn:

- The essentials of counter-controlled repetition.
- To use the `for` and `do...while` repetition statements to execute statements in a program repeatedly.
- To understand multiple selection using the `switch` selection statement.
- To use the `break` and `continue` program control statements to alter the flow of control.

## 5.1 Introduction

This chapter continues our presentation of structured programming theory and principles by introducing all but one of Java's remaining control statements. We demonstrate Java's `for`, `do...while` and `switch` statements. Through a series of short examples using `while` and `for`, we explore the essentials of counter-controlled repetition. We create a version of class `GradeBook` that uses a `switch` statement to count the number of A, B, C, D and F grade equivalents in a set of numeric grades entered by the user. We introduce the `break` and `continue` program-control statements. We discuss Java's logical operators, which enable you to use more complex conditional expressions in control statements. Finally, we summarize Java's control statements and the proven problem-solving techniques presented in this chapter and Chapter 4.

## 5.2 Essentials of Counter-Controlled Repetition

This section uses the `while` repetition statement introduced in Chapter 4 to formalize the elements required to perform counter-controlled repetition, which requires

1. a **control variable** (or loop counter)
2. the **initial value** of the control variable
3. the **increment** (or **decrement**) by which the control variable is modified each time through the loop (also known as **each iteration of the loop**)
4. the **loop-continuation condition** that determines if looping should continue.

To see these elements of counter-controlled repetition, consider the application of Fig. 5.1, which uses a loop to display the numbers from 1 through 10.

```

1 // Fig. 5.1: WhileCounter.java
2 // Counter-controlled repetition with the while repetition statement.
3
4 public class WhileCounter
5 {
6     public static void main( String[] args )
7     {

```

**Fig. 5.1** | Counter-controlled repetition with the `while` repetition statement. (Part 1 of 2.)

```

8      int counter = 1; // declare and initialize control variable
9
10     while ( counter <= 10 ) // loop-continuation condition
11     {
12         System.out.printf( "%d ", counter );
13         ++counter; // increment control variable by 1
14     } // end while
15
16     System.out.println(); // output a newline
17 } // end main
18 } // end class WhileCounter

```

```
1 2 3 4 5 6 7 8 9 10
```

**Fig. 5.1** | Counter-controlled repetition with the `while` repetition statement. (Part 2 of 2.)

In Fig. 5.1, the elements of counter-controlled repetition are defined in lines 8, 10 and 13. Line 8 declares the control variable (`counter`) as an `int`, reserves space for it in memory and sets its initial value to 1. Variable `counter` also could have been declared and initialized with the following local-variable declaration and assignment statements:

```

int counter; // declare counter
counter = 1; // initialize counter to 1

```

Line 12 displays control variable `counter`'s value during each iteration of the loop. Line 13 increments the control variable by 1 for each iteration of the loop. The loop-continuation condition in the `while` (line 10) tests whether the value of the control variable is less than or equal to 10 (the final value for which the condition is `true`). The program performs the body of this `while` even when the control variable is 10. The loop terminates when the control variable exceeds 10 (i.e., `counter` becomes 11).

### Common Programming Error 5.1

*Because floating-point values may be approximate, controlling loops with floating-point variables may result in imprecise counter values and inaccurate termination tests.*

### Error-Prevention Tip 5.1

*Use integers to control counting loops.*

The program in Fig. 5.1 can be made more concise by initializing `counter` to 0 in line 8 and preincrementing `counter` in the `while` condition as follows:

```

while ( ++counter <= 10 ) // loop-continuation condition
    System.out.printf( "%d ", counter );

```

This code saves a statement (and eliminates the need for braces around the loop's body), because the `while` condition performs the increment before testing the condition. (Recall from Section 4.12 that the precedence of `++` is higher than that of `<=`.) Coding in such a condensed fashion takes practice, might make code more difficult to read, debug, modify and maintain, and typically should be avoided.

### Software Engineering Observation 5.1

*“Keep it simple” is good advice for most of the code you’ll write.*

## 5.3 for Repetition Statement

Section 5.2 presented the essentials of counter-controlled repetition. The `while` statement can be used to implement any counter-controlled loop. Java also provides the **for repetition statement**, which specifies the counter-controlled-repetition details in a single line of code. Figure 5.2 reimplements the application of Fig. 5.1 using `for`.

```

1 // Fig. 5.2: ForCounter.java
2 // Counter-controlled repetition with the for repetition statement.
3
4 public class ForCounter
5 {
6     public static void main( String[] args )
7     {
8         // for statement header includes initialization,
9         // loop-continuation condition and increment
10        for ( int counter = 1; counter <= 10; counter++ )
11            System.out.printf( "%d ", counter );
12
13        System.out.println(); // output a newline
14    } // end main
15 } // end class ForCounter

```

1 2 3 4 5 6 7 8 9 10

**Fig. 5.2** | Counter-controlled repetition with the `for` repetition statement.

When the `for` statement (lines 10–11) begins executing, the control variable `counter` is declared and initialized to 1. (Recall from Section 5.2 that the first two elements of counter-controlled repetition are the control variable and its initial value.) Next, the program checks the loop-continuation condition, `counter <= 10`, which is between the two required semicolons. Because the initial value of `counter` is 1, the condition initially is true. Therefore, the body statement (line 11) displays control variable `counter`’s value, namely 1. After executing the loop’s body, the program increments `counter` in the expression `counter++`, which appears to the right of the second semicolon. Then the loop-continuation test is performed again to determine whether the program should continue with the next iteration of the loop. At this point, the control variable’s value is 2, so the condition is still true (the final value is not exceeded)—thus, the program performs the body statement again (i.e., the next iteration of the loop). This process continues until the numbers 1 through 10 have been displayed and the `counter`’s value becomes 11, causing the loop-continuation test to fail and repetition to terminate (after 10 repetitions of the loop body). Then the program performs the first statement after the `for`—in this case, line 13.

Figure 5.2 uses (in line 10) the loop-continuation condition `counter <= 10`. If you incorrectly specified `counter < 10` as the condition, the loop would iterate only nine times. This is a common logic error called an **off-by-one error**.

### Common Programming Error 5.2

Using an incorrect relational operator or an incorrect final value of a loop counter in the loop-continuation condition of a repetition statement can cause an off-by-one error.

### Error-Prevention Tip 5.2

Using the final value in the condition of a `while` or `for` statement and using the `<=` relational operator helps avoid off-by-one errors. For a loop that prints the values 1 to 10, the loop-continuation condition should be `counter <= 10` rather than `counter < 10` (which causes an off-by-one error) or `counter < 11` (which is correct). Many programmers prefer so-called zero-based counting, in which to count 10 times, `counter` would be initialized to zero and the loop-continuation test would be `counter < 10`.

### A Closer Look at the `for` Statement's Header

Figure 5.3 takes a closer look at the `for` statement in Fig. 5.2. The `for`'s first line (including the keyword `for` and everything in parentheses after `for`)—line 10 in Fig. 5.2—is sometimes called the **for statement header**. The `for` header “does it all”—it specifies each item needed for counter-controlled repetition with a control variable. If there's more than one statement in the body of the `for`, braces are required to define the body of the loop.

**Fig. 5.3** | `for` statement header components.

### General Format of a `for` Statement

The general format of the `for` statement is

```

for ( initialization; loopContinuationCondition; increment )
    statement
  
```

where the *initialization* expression names the loop's control variable and optionally provides its initial value, *loopContinuationCondition* determines whether the loop should continue executing and *increment* modifies the control variable's value (possibly an increment or decrement), so that the loop-continuation condition eventually becomes false. The two semicolons in the `for` header are required. If the loop-continuation condition is initially false, the program does *not* execute the `for` statement's body. Instead, execution proceeds with the statement following the `for`.

### Representing a `for` Statement with an Equivalent `while` Statement

In most cases, the `for` statement can be represented with an equivalent `while` statement as follows:

```

initialization;
while ( loopContinuationCondition )
{
    statement
    increment;
}

```

In Section 5.7, we show a case in which a `for` statement cannot be represented with an equivalent `while` statement.

Typically, `for` statements are used for counter-controlled repetition and `while` statements for sentinel-controlled repetition. However, `while` and `for` can each be used for either repetition type.

### Scope of a `for` Statement's Control Variable

If the *initialization* expression in the `for` header declares the control variable (i.e., the control variable's type is specified before the variable name, as in Fig. 5.2), the control variable can be used *only* in that `for` statement—it will not exist outside it. This restricted use is known as the variable's **scope**. The scope of a variable defines where it can be used in a program. For example, a local variable can be used *only* in the method that declares it and *only* from the point of declaration through the end of the method. Scope is discussed in detail in Chapter 6, *Methods: A Deeper Look*.

#### Common Programming Error 5.3

When a `for` statement's control variable is declared in the initialization section of the `for`'s header, using the control variable after the `for`'s body is a compilation error.

### Expressions in a `for` Statement's Header Are Optional

All three expressions in a `for` header are optional. If the *loopContinuationCondition* is omitted, Java assumes that the loop-continuation condition is always true, thus creating an infinite loop. You might omit the *initialization* expression if the program initializes the control variable before the loop. You might omit the *increment* expression if the program calculates the increment with statements in the loop's body or if no increment is needed. The increment expression in a `for` acts as if it were a standalone statement at the end of the `for`'s body. Therefore, the expressions

```

counter = counter + 1
counter += 1
++counter
counter++

```

are equivalent increment expressions in a `for` statement. Many programmers prefer `counter++` because it's concise and because a `for` loop evaluates its increment expression *after* its body executes, so the postfix increment form seems more natural. In this case, the variable being incremented does not appear in a larger expression, so preincrementing and postincrementing actually have the same effect.

#### Common Programming Error 5.4

Placing a semicolon immediately to the right of the right parenthesis of a `for` header makes that `for`'s body an empty statement. This is normally a logic error.

### Error-Prevention Tip 5.3

Infinite loops occur when the loop-continuation condition in a repetition statement never becomes false. To prevent this situation in a counter-controlled loop, ensure that the control variable is incremented (or decremented) during each iteration of the loop. In a sentinel-controlled loop, ensure that the sentinel value is able to be input.

### Placing Arithmetic Expressions in a For Statement's Header

The initialization, loop-continuation condition and increment portions of a for statement can contain arithmetic expressions. For example, assume that  $x = 2$  and  $y = 10$ . If  $x$  and  $y$  are not modified in the body of the loop, the statement

```
for ( int j = x; j <= 4 * x * y; j += y / x )
```

is equivalent to the statement

```
for ( int j = 2; j <= 80; j += 5 )
```

The increment of a for statement may also be *negative*, in which case it's really a *decrement*, and the loop counts *downward*.

### Using a For Statement's Control Variable in the Statements's Body

Programs frequently display the control-variable value or use it in calculations in the loop body, but this use is not required. The control variable is commonly used to control repetition without being mentioned in the body of the for.

### Error-Prevention Tip 5.4

Although the value of the control variable can be changed in the body of a for loop, avoid doing so, because this practice can lead to subtle errors.

### UML Activity Diagram for the For Statement

The for statement's UML activity diagram is similar to that of the while statement (Fig. 4.4). Figure 5.4 shows the activity diagram of the for statement in Fig. 5.2. The

**Fig. 5.4** | UML activity diagram for the for statement in Fig. 5.2.

diagram makes it clear that initialization occurs *once before* the loop-continuation test is evaluated the first time, and that incrementing occurs *each* time through the loop *after* the body statement executes.

## 5.4 Examples Using the for Statement

The following examples show techniques for varying the control variable in a for statement. In each case, we write the appropriate for header. Note the change in the relational operator for loops that decrement the control variable.

- a) Vary the control variable from 1 to 100 in increments of 1.

```
for ( int i = 1; i <= 100; i++ )
```

- b) Vary the control variable from 100 to 1 in decrements of 1.

```
for ( int i = 100; i >= 1; i-- )
```

- c) Vary the control variable from 7 to 77 in increments of 7.

```
for ( int i = 7; i <= 77; i += 7 )
```

- d) Vary the control variable from 20 to 2 in decrements of 2.

```
for ( int i = 20; i >= 2; i -= 2 )
```

- e) Vary the control variable over the values 2, 5, 8, 11, 14, 17, 20.

```
for ( int i = 2; i <= 20; i += 3 )
```

- f) Vary the control variable over the values 99, 88, 77, 66, 55, 44, 33, 22, 11, 0.

```
for ( int i = 99; i >= 0; i -= 11 )
```

### Common Programming Error 5.5

Using an incorrect relational operator in the loop-continuation condition of a loop that counts downward (e.g., using  $i \leq 1$  instead of  $i \geq 1$  in a loop counting down to 1) is usually a logic error.

### Application: Summing the Even Integers from 2 to 20

We now consider two sample applications that demonstrate simple uses of for. The application in Fig. 5.5 uses a for statement to sum the even integers from 2 to 20 and store the result in an int variable called total.

```
1 // Fig. 5.5: Sum.java
2 // Summing integers with the for statement.
3
4 public class Sum
5 {
6     public static void main( String[] args )
7     {
8         int total = 0; // initialize total
9     }
```

**Fig. 5.5** | Summing integers with the for statement. (Part I of 2.)

```

10     // total even integers from 2 through 20
11     for ( int number = 2; number <= 20; number += 2 )
12         total += number;
13
14     System.out.printf( "Sum is %d\n", total ); // display results
15 } // end main
16 } // end class Sum

```

```
Sum is 110
```

**Fig. 5.5** | Summing integers with the for statement. (Part 2 of 2.)

The *initialization* and *increment* expressions can be comma-separated lists that enable you to use multiple initialization expressions or multiple increment expressions. For example, *although this is discouraged*, you could merge the body of the for statement in lines 11–12 of Fig. 5.5 into the increment portion of the for header by using a comma as follows:

```

for ( int number = 2; number <= 20; total += number, number += 2 )
; // empty statement

```

### Good Programming Practice 5.1

*For readability limit the size of control-statement headers to a single line if possible.*

### Application: Compound-Interest Calculations

Let's use the for statement to compute compound interest. Consider the following problem:

*A person invests \$1000 in a savings account yielding 5% interest. Assuming that all the interest is left on deposit, calculate and print the amount of money in the account at the end of each year for 10 years. Use the following formula to determine the amounts:*

$$a = p(1 + r)^n$$

where

$p$  is the original amount invested (i.e., the principal)

$r$  is the annual interest rate (e.g., use 0.05 for 5%)

$n$  is the number of years

$a$  is the amount on deposit at the end of the  $n$ th year.

The solution to this problem (Fig. 5.6) involves a loop that performs the indicated calculation for each of the 10 years the money remains on deposit. Lines 8–10 in method `main` declare `double` variables `amount`, `principal` and `rate`, and initialize `principal` to 1000.0 and `rate` to 0.05. Java treats floating-point constants like 1000.0 and 0.05 as type `double`. Similarly, Java treats whole-number constants like 7 and -22 as type `int`.

```

1 // Fig. 5.6: Interest.java
2 // Compound-interest calculations with for.
3
4 public class Interest
5 {

```

**Fig. 5.6** | Compound-interest calculations with for. (Part 1 of 2.)

```

6   public static void main( String[] args )
7   {
8       double amount; // amount on deposit at end of each year
9       double principal = 1000.0; // initial amount before interest
10      double rate = 0.05; // interest rate
11
12      // display headers
13      System.out.printf( "%s%20s\n", "Year", "Amount on deposit" );
14
15      // calculate amount on deposit for each of ten years
16      for ( int year = 1; year <= 10; year++ )
17      {
18          // calculate new amount for specified year
19          amount = principal * Math.pow( 1.0 + rate, year );
20
21          // display the year and the amount
22          System.out.printf( "%4d%,20.2f\n", year, amount );
23      } // end for
24  } // end main
25 } // end class Interest

```

Year	Amount on deposit
1	1,050.00
2	1,102.50
3	1,157.63
4	1,215.51
5	1,276.28
6	1,340.10
7	1,407.10
8	1,477.46
9	1,551.33
10	1,628.89

**Fig. 5.6** | Compound-interest calculations with for. (Part 2 of 2.)

### *Formatting Strings with Field Widths and Justification*

Line 13 outputs the headers for two columns of output. The first column displays the year and the second column the amount on deposit at the end of that year. We use the format specifier `%20s` to output the String "Amount on Deposit". The integer 20 between the `%` and the conversion character `s` indicates that the value should be displayed with a **field width** of 20—that is, `printf` displays the value with at least 20 character positions. If the value to be output is less than 20 character positions wide (17 characters in this example), the value is **right justified** in the field by default. If the year value to be output were more than four character positions wide, the field width would be extended to the right to accommodate the entire value—this would push the amount field to the right, upsetting the neat columns of our tabular output. To output values **left justified**, simply precede the field width with the **minus sign (-) formatting flag** (e.g., `%-20s`).

### *Performing the Interest Calculations*

The for statement (lines 16–23) executes its body 10 times, varying control variable `year` from 1 to 10 in increments of 1. This loop terminates when `year` becomes 11. (Variable `year` represents  $n$  in the problem statement.)

Classes provide methods that perform common tasks on objects. In fact, most methods must be called on a specific object. For example, to output text in Fig. 5.6, line 13 calls method `printf` on the `System.out` object. Many classes also provide methods that perform common tasks and do *not* require objects. These are called *static* methods. For example, Java does not include an exponentiation operator, so the designers of Java's `Math` class defined *static* method `pow` for raising a value to a power. You can call a *static* method by specifying the class name followed by a dot (`.`) and the method name, as in

```
ClassName.methodName( arguments )
```

In Chapter 6, you'll learn how to implement *static* methods in your own classes.

We use *static* method `pow` of class `Math` to perform the compound-interest calculation in Fig. 5.6. `Math.pow(x, y)` calculates the value of  $x$  raised to the  $y^{\text{th}}$  power. The method receives two `double` arguments and returns a `double` value. Line 19 performs the calculation  $a = p(1 + r)^n$ , where  $a$  is amount,  $p$  is principal,  $r$  is rate and  $n$  is year. Class `Math` is defined in package `java.lang`, so you do *not* need to import class `Math` to use it.

The body of the `for` statement contains the calculation `1.0 + rate`, which appears as an argument to the `Math.pow` method. In fact, this calculation produces the same result each time through the loop, so repeating it every iteration of the loop is wasteful.

### Performance Tip 5.1

*In loops, avoid calculations for which the result never changes—such calculations should typically be placed before the loop. Many of today's sophisticated optimizing compilers will place such calculations outside loops in the compiled code.*

### Formatting Floating-Point Numbers

After each calculation, line 22 outputs the year and the amount on deposit at the end of that year. The year is output in a field width of four characters (as specified by `%4d`). The amount is output as a floating-point number with the format specifier `%,20.2f`. The **comma (,) formatting flag** indicates that the floating-point value should be output with a **grouping separator**. The actual separator used is specific to the user's locale (i.e., country). For example, in the United States, the number will be output using commas to separate every three digits and a decimal point to separate the fractional part of the number, as in 1,234.45. The number 20 in the format specification indicates that the value should be output right justified in a field width of 20 characters. The `.2` specifies the formatted number's precision—in this case, the number is rounded to the nearest hundredth and output with two digits to the right of the decimal point.

### A Warning about Displaying Rounded Values

We declared variables `amount`, `principal` and `rate` to be of type `double` in this example. We're dealing with fractional parts of dollars and thus need a type that allows decimal points in its values. Unfortunately, floating-point numbers can cause trouble. Here's a simple explanation of what can go wrong when using `double` (or `float`) to represent dollar amounts (assuming that dollar amounts are displayed with two digits to the right of the decimal point): Two `double` dollar amounts stored in the machine could be 14.234 (which would normally be rounded to 14.23 for display purposes) and 18.673 (which would normally be rounded to 18.67 for display purposes). When these amounts are added, they produce the internal sum 32.907, which would normally be rounded to 32.91 for display purposes. Thus, your output could appear as

```

14.23
+ 18.67
-----
32.91

```

but a person adding the individual numbers as displayed would expect the sum to be 32.90. You've been warned!

### Error-Prevention Tip 5.5

Do not use variables of type `double` (or `float`) to perform precise monetary calculations. The imprecision of floating-point numbers can cause errors. In the exercises, you'll learn how to use integers to perform precise monetary calculations. Java also provides class `java.math.BigDecimal` to perform precise monetary calculations. For more information, see [download.oracle.com/javase/6/docs/api/java/math/BigDecimal.html](http://download.oracle.com/javase/6/docs/api/java/math/BigDecimal.html).

## 5.5 do...while Repetition Statement

The **do...while repetition statement** is similar to the `while` statement. In the `while`, the program tests the loop-continuation condition at the beginning of the loop, before executing the loop's body; if the condition is false, the body *never* executes. The `do...while` statement tests the loop-continuation condition *after* executing the loop's body; therefore, *the body always executes at least once*. When a `do...while` statement terminates, execution continues with the next statement in sequence. Figure 5.7 uses a `do...while` (lines 10–14) to output the numbers 1–10.

```

1 // Fig. 5.7: DoWhileTest.java
2 // do...while repetition statement.
3
4 public class DoWhileTest
5 {
6     public static void main( String[] args )
7     {
8         int counter = 1; // initialize counter
9
10        do
11        {
12            System.out.printf( "%d ", counter );
13            ++counter;
14        } while ( counter <= 10 ); // end do...while
15
16        System.out.println(); // outputs a newline
17    } // end main
18 } // end class DoWhileTest

```

```
1 2 3 4 5 6 7 8 9 10
```

**Fig. 5.7** | do...while repetition statement.

Line 8 declares and initializes control variable `counter`. Upon entering the `do...while` statement, line 12 outputs `counter`'s value and line 13 increments `counter`. Then the pro-

gram evaluates the loop-continuation test at the *bottom* of the loop (line 14). If the condition is true, the loop continues from the first body statement (line 12). If the condition is false, the loop terminates and the program continues with the next statement after the loop.

Figure 5.8 contains the UML activity diagram for the `do...while` statement. This diagram makes it clear that the loop-continuation condition is not evaluated until *after* the loop performs the action state at least once. Compare this activity diagram with that of the `while` statement (Fig. 4.4).

**Fig. 5.8** | `do...while` repetition statement UML activity diagram.

It isn't necessary to use braces in the `do...while` repetition statement if there's only one statement in the body. However, many programmers include the braces, to avoid confusion between the `while` and `do...while` statements. For example,

```
while ( condition )
```

is normally the first line of a `while` statement. A `do...while` statement with no braces around a single-statement body appears as:

```
do
    statement
while ( condition );
```

which can be confusing. A reader may misinterpret the last line—`while( condition );`—as a `while` statement containing an empty statement (the semicolon by itself). Thus, the `do...while` statement with one body statement is usually written as follows:

```
do
{
    statement
} while ( condition );
```

### Good Programming Practice 5.2

Always include braces in a `do...while` statement. This helps eliminate ambiguity between the `while` statement and a `do...while` statement containing only one statement.

## 5.6 switch Multiple-Selection Statement

Chapter 4 discussed the `if` single-selection statement and the `if...else` double-selection statement. The **switch multiple-selection statement** performs different actions based on the possible values of a **constant integral expression** of type `byte`, `short`, `int` or `char`.

### *GradeBook Class with switch Statement to Count A, B, C, D and F Grades*

Figure 5.9 enhances class `GradeBook` from Chapters 3–4. The new version we now present not only calculates the average of a set of numeric grades entered by the user, but uses a `switch` statement to determine whether each grade is the equivalent of an A, B, C, D or F and to increment the appropriate grade counter. The class also displays a summary of the number of students who received each grade. Refer to Fig. 5.10 for sample inputs and outputs of the `GradeBookTest` application that uses class `GradeBook` to process a set of grades.

```

1 // Fig. 5.9: GradeBook.java
2 // GradeBook class uses switch statement to count letter grades.
3 import java.util.Scanner; // program uses class Scanner
4
5 public class GradeBook
6 {
7     private String courseName; // name of course this GradeBook represents
8     // int instance variables are initialized to 0 by default
9     private int total; // sum of grades
10    private int gradeCounter; // number of grades entered
11    private int aCount; // count of A grades
12    private int bCount; // count of B grades
13    private int cCount; // count of C grades
14    private int dCount; // count of D grades
15    private int fCount; // count of F grades
16
17    // constructor initializes courseName;
18    public GradeBook( String name )
19    {
20        courseName = name; // initializes courseName
21    } // end constructor
22
23    // method to set the course name
24    public void setCourseName( String name )
25    {
26        courseName = name; // store the course name
27    } // end method setCourseName
28
29    // method to retrieve the course name
30    public String getCourseName()
31    {

```

**Fig. 5.9** | `GradeBook` class uses `switch` statement to count letter grades. (Part 1 of 3.)

```
32     return courseName;
33 } // end method getCourseName
34
35 // display a welcome message to the GradeBook user
36 public void displayMessage()
37 {
38     // getCourseName gets the name of the course
39     System.out.printf( "Welcome to the grade book for\n%s!\n\n",
40         getCourseName() );
41 } // end method displayMessage
42
43 // input arbitrary number of grades from user
44 public void inputGrades()
45 {
46     Scanner input = new Scanner( System.in );
47
48     int grade; // grade entered by user
49
50     System.out.printf( "%s\n%s\n  %s\n  %s\n",
51         "Enter the integer grades in the range 0-100.",
52         "Type the end-of-file indicator to terminate input:",
53         "On UNIX/Linux/Mac OS X type <Ctrl> d then press Enter",
54         "On Windows type <Ctrl> z then press Enter" );
55
56     // loop until user enters the end-of-file indicator
57     while ( input.hasNext() )
58     {
59         grade = input.nextInt(); // read grade
60         total += grade; // add grade to total
61         ++gradeCounter; // increment number of grades
62
63         // call method to increment appropriate counter
64         incrementLetterGradeCounter( grade );
65     } // end while
66 } // end method inputGrades
67
68 // add 1 to appropriate counter for specified grade
69 private void incrementLetterGradeCounter( int grade )
70 {
71     // determine which grade was entered
72     switch ( grade / 10 )
73     {
74         case 9: // grade was between 90
75             case 10: // and 100, inclusive
76                 ++aCount; // increment aCount
77                 break; // necessary to exit switch
78
79             case 8: // grade was between 80 and 89
80                 ++bCount; // increment bCount
81                 break; // exit switch
82     }
```

**Fig. 5.9** | GradeBook class uses switch statement to count letter grades. (Part 2 of 3.)

```

83     case 7: // grade was between 70 and 79
84         ++cCount; // increment cCount
85         break; // exit switch
86
87     case 6: // grade was between 60 and 69
88         ++dCount; // increment dCount
89         break; // exit switch
90
91     default: // grade was less than 60
92         ++fCount; // increment fCount
93         break; // optional; will exit switch anyway
94 } // end switch
95 } // end method incrementLetterGradeCounter
96
97 // display a report based on the grades entered by the user
98 public void displayGradeReport()
99 {
100     System.out.println( "\nGrade Report:" );
101
102     // if user entered at least one grade...
103     if ( gradeCounter != 0 )
104     {
105         // calculate average of all grades entered
106         double average = (double) total / gradeCounter;
107
108         // output summary of results
109         System.out.printf( "Total of the %d grades entered is %d\n",
110             gradeCounter, total );
111         System.out.printf( "Class average is %.2f\n", average );
112         System.out.printf( "%s\n%s%d\n%s%d\n%s%d\n%s%d\n%s%d\n",
113             "Number of students who received each grade:",
114             "A: ", aCount, // display number of A grades
115             "B: ", bCount, // display number of B grades
116             "C: ", cCount, // display number of C grades
117             "D: ", dCount, // display number of D grades
118             "F: ", fCount ); // display number of F grades
119     } // end if
120     else // no grades were entered, so output appropriate message
121         System.out.println( "No grades were entered" );
122 } // end method displayGradeReport
123 } // end class GradeBook

```

**Fig. 5.9** | GradeBook class uses switch statement to count letter grades. (Part 3 of 3.)

Like earlier versions of the class, class `GradeBook` (Fig. 5.9) declares instance variable `courseName` (line 7) and contains methods `setCourseName` (lines 24–27), `getCourseName` (lines 30–33) and `displayMessage` (lines 36–41), which set the course name, store the course name and display a welcome message to the user, respectively. The class also contains a constructor (lines 18–21) that initializes the course name.

Class `GradeBook` also declares instance variables `total` (line 9) and `gradeCounter` (line 10), which keep track of the sum of the grades entered by the user and the number of grades entered, respectively. Lines 11–15 declare counter variables for each grade category. Class `GradeBook` maintains `total`, `gradeCounter` and the five letter-grade counters

as instance variables so that they can be used or modified in any of the class's methods. The class's constructor (lines 18–21) sets only the course name, because the remaining seven instance variables are `ints` and are initialized to 0 by default.

Class `GradeBook` (Fig. 5.9) contains three additional methods—`inputGrades`, `incrementLetterGradeCounter` and `displayGradeReport`. Method `inputGrades` (lines 44–66) reads an arbitrary number of integer grades from the user using sentinel-controlled repetition and updates instance variables `total` and `gradeCounter`. This method calls method `incrementLetterGradeCounter` (lines 69–95) to update the appropriate letter-grade counter for each grade entered. Method `displayGradeReport` (lines 98–122) outputs a report containing the total of all grades entered, the average of the grades and the number of students who received each letter grade. Let's examine these methods in more detail.

### *Method `inputGrades`*

Line 48 in method `inputGrades` declares variable `grade`, which will store the user's input. Lines 50–54 prompt the user to enter integer grades and to type the end-of-file indicator to terminate the input. The **end-of-file indicator** is a system-dependent keystroke combination which the user enters to indicate that there's no more data to input. In Chapter 17, Files, Streams and Object Serialization, we'll see how the end-of-file indicator is used when a program reads its input from a file.

On UNIX/Linux/Mac OS X systems, end-of-file is entered by typing the sequence

```
<Ctrl> d
```

on a line by itself. This notation means to simultaneously press both the `Ctrl` key and the `d` key. On Windows systems, end-of-file can be entered by typing

```
<Ctrl> z
```

[*Note:* On some systems, you must press `Enter` after typing the end-of-file key sequence. Also, Windows typically displays the characters `^Z` on the screen when the end-of-file indicator is typed, as shown in the output of Fig. 5.10.]

### **Portability Tip 5.1**

*The keystroke combinations for entering end-of-file are system dependent.*

The `while` statement (lines 57–65) obtains the user input. The condition at line 57 calls Scanner method `hasNext` to determine whether there's more data to input. This method returns the `boolean` value `true` if there's more data; otherwise, it returns `false`. The returned value is then used as the value of the condition in the `while` statement. Method `hasNext` returns `false` once the user types the end-of-file indicator.

Line 59 inputs a grade value from the user. Line 60 adds `grade` to `total`. Line 61 increments `gradeCounter`. The class's `displayGradeReport` method uses these variables to compute the average of the grades. Line 64 calls the class's `incrementLetterGradeCounter` method (declared in lines 69–95) to increment the appropriate letter-grade counter based on the numeric grade entered.

### *Method `incrementLetterGradeCounter`*

Method `incrementLetterGradeCounter` contains a `switch` statement (lines 72–94) that determines which counter to increment. We assume that the user enters a valid grade in

the range 0–100. A grade in the range 90–100 represents A, 80–89 represents B, 70–79 represents C, 60–69 represents D and 0–59 represents F. The `switch` statement consists of a block that contains a sequence of **case labels** and an optional **default case**. These are used in this example to determine which counter to increment based on the grade.

When the flow of control reaches the `switch`, the program evaluates the expression in the parentheses (`grade / 10`) following keyword `switch`. This is the `switch`'s **controlling expression**. The program compares this expression's value (which must evaluate to an integral value of type `byte`, `char`, `short` or `int`) with each case label. The controlling expression in line 72 performs integer division, which *truncates the fractional part* of the result. Thus, when we divide a value from 0 to 100 by 10, the result is always a value from 0 to 10. We use several of these values in our case labels. For example, if the user enters the integer 85, the controlling expression evaluates to 8. The `switch` compares 8 with each case label. If a match occurs (case 8: at line 79), the program executes that case's statements. For the integer 8, line 80 increments `bCount`, because a grade in the 80s is a B. The **break statement** (line 81) causes program control to proceed with the first statement after the `switch`—in this program, we reach the end of method `incrementLetterGradeCounter`'s body, so the method terminates and control returns to line 65 in method `inputGrades` (the first line after the call to `incrementLetterGradeCounter`). Line 65 is the end of a `while` loop's body, so control flows to the `while`'s condition (line 57) to determine whether the loop should continue executing.

The cases in our `switch` explicitly test for the values 10, 9, 8, 7 and 6. Note the cases at lines 74–75 that test for the values 9 and 10 (both of which represent the grade A). Listing cases consecutively in this manner with no statements between them enables the cases to perform the same set of statements—when the controlling expression evaluates to 9 or 10, the statements in lines 76–77 will execute. The `switch` statement does not provide a mechanism for testing ranges of values, so every value you need to test must be listed in a separate case label. Each case can have multiple statements. The `switch` statement differs from other control statements in that it does *not* require braces around multiple statements in a case.

Without `break` statements, each time a match occurs in the `switch`, the statements for that case and subsequent cases execute until a `break` statement or the end of the `switch` is encountered. This is often referred to as “falling through” to the statements in subsequent cases. (This feature is perfect for writing a concise program that displays the iterative song “The Twelve Days of Christmas” in Exercise 5.29.)

### Common Programming Error 5.6

*Forgetting a break statement when one is needed in a switch is a logic error.*

If no match occurs between the controlling expression's value and a case label, the `default` case (lines 91–93) executes. We use the `default` case in this example to process all controlling-expression values that are less than 6—that is, all failing grades. If no match occurs and the `switch` does not contain a `default` case, program control simply continues with the first statement after the `switch`.

### GradeBookTest Class That Demonstrates Class GradeBook

Class `GradeBookTest` (Fig. 5.10) creates a `GradeBook` object (lines 10–11). Line 13 invokes the object's `displayMessage` method to output a welcome message to the user. Line 14 invokes the object's `inputGrades` method to read a set of grades from the user and keep

track of the sum of all the grades entered and the number of grades. Recall that method `inputGrades` also calls method `incrementLetterGradeCounter` to keep track of the number of students who received each letter grade. Line 15 invokes method `displayGradeReport` of class `GradeBook`, which outputs a report based on the grades entered (as in the input/output window in Fig. 5.10). Line 103 of class `GradeBook` (Fig. 5.9) determines whether the user entered at least one grade—this helps us avoid dividing by zero. If so, line 106 calculates the average of the grades. Lines 109–118 then output the total of all the grades, the class average and the number of students who received each letter grade. If no grades were entered, line 121 outputs an appropriate message. The output in Fig. 5.10 shows a sample grade report based on 10 grades.

```

1 // Fig. 5.10: GradeBookTest.java
2 // Create GradeBook object, input grades and display grade report.
3
4 public class GradeBookTest
5 {
6     public static void main( String[] args )
7     {
8         // create GradeBook object myGradeBook and
9         // pass course name to constructor
10        GradeBook myGradeBook = new GradeBook(
11            "CS101 Introduction to Java Programming" );
12
13        myGradeBook.displayMessage(); // display welcome message
14        myGradeBook.inputGrades(); // read grades from user
15        myGradeBook.displayGradeReport(); // display report based on grades
16    } // end main
17 } // end class GradeBookTest

```

```

Welcome to the grade book for
CS101 Introduction to Java Programming!

Enter the integer grades in the range 0-100.
Type the end-of-file indicator to terminate input:
    On UNIX/Linux/Mac OS X type <Ctrl> d then press Enter
    On Windows type <Ctrl> z then press Enter
99
92
45
57
63
71

90
100
^Z

Grade Report:
Total of the 10 grades entered is 778
Class average is 77.80

```

**Fig. 5.10** | Create `GradeBook` object, input grades and display grade report. (Part 1 of 2.)

Number of students who received each grade:  
 A: 4  
 B: 1  
 C: 2  
 D: 1  
 F: 2

**Fig. 5.10** | Create GradeBook object, input grades and display grade report. (Part 2 of 2.)

Class GradeBookTest (Fig. 5.10) does not directly call GradeBook method `incrementLetterGradeCounter` (lines 69–95 of Fig. 5.9). This method is used exclusively by method `inputGrades` of class GradeBook to update the appropriate letter-grade counter as each new grade is entered by the user. Method `incrementLetterGradeCounter` exists solely to support the operations of GradeBook’s other methods, so it’s declared private.

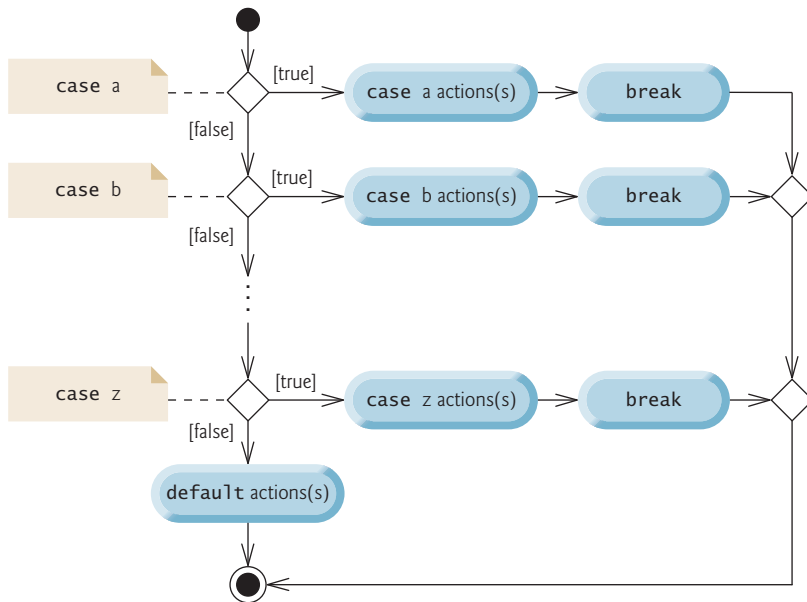

**Software Engineering Observation 5.2**

Recall from Chapter 3 that methods declared with access modifier `private` can be called only by other methods of the class in which the private methods are declared. Such methods are commonly referred to as *utility methods* or *helper methods* because they’re typically used to support the operation of the class’s other methods.

**switch Statement UML Activity Diagram**

Figure 5.11 shows the UML activity diagram for the general switch statement. Most `switch` statements use a `break` in each case to terminate the `switch` statement after processing the case. Figure 5.11 emphasizes this by including `break` statements in the activity

**Fig. 5.11** | `switch` multiple-selection statement UML activity diagram with `break` statements.

diagram. The diagram makes it clear that the `break` statement at the end of a case causes control to exit the `switch` statement immediately.

The `break` statement is not required for the `switch`'s last case (or the optional default case, when it appears last), because execution continues with the next statement after the `switch`.

### Software Engineering Observation 5.3

*Provide a default case in `switch` statements. Including a default case focuses you on the need to process exceptional conditions.*

### Good Programming Practice 5.3

*Although each case and the default case in a `switch` can occur in any order, place the default case last. When the default case is listed last, the `break` for that case is not required.*

### *Notes on the Expression in Each case of a `switch`*

When using the `switch` statement, remember that each case must contain a constant integral expression—that is, any combination of integer constants that evaluates to a constant integer value (e.g., `-7`, `0` or `221`). An integer constant is simply an integer value. In addition, you can use **character constants**—specific characters in single quotes, such as `'A'`, `'7'` or `'$'`—which represent the integer values of characters and enum constants (introduced in Section 6.10). (Appendix B shows the integer values of the characters in the ASCII character set, which is a subset of the Unicode character set used by Java.)

The expression in each case can also be a **constant variable**—a variable containing a value which does not change for the entire program. Such a variable is declared with keyword `final` (discussed in Chapter 6). Java has a feature called *enumerations*, which we also present in Chapter 6. Enumeration constants can also be used in case labels. In Chapter 10, Object-Oriented Programming: Polymorphism, we present a more elegant way to implement `switch` logic—we use a technique called *polymorphism* to create programs that are often clearer, easier to maintain and easier to extend than programs using `switch` logic.

### *Using Strings in `switch` Statements (New in Java SE 7)*

As of Java SE 7, you can use `Strings` in a `switch` statement's controlling expression and in case labels. For example, you might want to use a city's name to obtain the corresponding ZIP code. Assuming that `city` and `zipCode` are `String` variables, the following `switch` statement performs this task for three cities:

```
switch( city )
{
    case "Maynard":
        zipCode = "01754";
        break;
    case "Marlborough":
        zipCode = "01752";
        break;
    case "Framingham":
        zipCode = "01701";
        break;
} // end switch
```

## 5.7 break and continue Statements

In addition to selection and repetition statements, Java provides statements `break` and `continue` (presented in this section and Appendix O) to alter the flow of control. The preceding section showed how `break` can be used to terminate a `switch` statement's execution. This section discusses how to use `break` in repetition statements.

### *break Statement*

The `break` statement, when executed in a `while`, `for`, `do...while` or `switch`, causes immediate exit from that statement. Execution continues with the first statement after the control statement. Common uses of the `break` statement are to escape early from a loop or to skip the remainder of a `switch` (as in Fig. 5.9). Figure 5.12 demonstrates a `break` statement exiting a `for`.

```

1 // Fig. 5.12: BreakTest.java
2 // break statement exiting a for statement.
3 public class BreakTest
4 {
5     public static void main( String[] args )
6     {
7         int count; // control variable also used after loop terminates
8
9         for ( count = 1; count <= 10; count++ ) // loop 10 times
10        {
11            if ( count == 5 ) // if count is 5,
12                break; // terminate loop
13
14            System.out.printf( "%d ", count );
15        } // end for
16
17        System.out.printf( "\nBroke out of loop at count = %d\n", count );
18    } // end main
19 } // end class BreakTest

```

```

1 2 3 4
Broke out of loop at count = 5

```

**Fig. 5.12** | `break` statement exiting a `for` statement.

When the `if` statement nested at lines 11–12 in the `for` statement (lines 9–15) detects that `count` is 5, the `break` statement at line 12 executes. This terminates the `for` statement, and the program proceeds to line 17 (immediately after the `for` statement), which displays a message indicating the value of the control variable when the loop terminated. The loop fully executes its body only four times instead of 10.

### *continue Statement*

The `continue` statement, when executed in a `while`, `for` or `do...while`, skips the remaining statements in the loop body and proceeds with the *next iteration* of the loop. In `while` and `do...while` statements, the program evaluates the loop-continuation test immediately after the `continue` statement executes. In a `for` statement, the increment expression executes, then the program evaluates the loop-continuation test.

```

1 // Fig. 5.13: ContinueTest.java
2 // continue statement terminating an iteration of a for statement.
3 public class ContinueTest
4 {
5     public static void main( String[] args )
6     {
7         for ( int count = 1; count <= 10; count++ ) // loop 10 times
8         {
9             if ( count == 5 ) // if count is 5,
10                continue; // skip remaining code in loop
11
12             System.out.printf( "%d ", count );
13         } // end for
14
15         System.out.println( "\nUsed continue to skip printing 5" );
16     } // end main
17 } // end class ContinueTest

```

```

1 2 3 4 6 7 8 9 10
Used continue to skip printing 5

```

**Fig. 5.13** | continue statement terminating an iteration of a for statement.

Figure 5.13 uses `continue` to skip the statement at line 12 when the nested `if` (line 9) determines that `count`'s value is 5. When the `continue` statement executes, program control continues with the increment of the control variable in the `for` statement (line 7).

In Section 5.3, we stated that `while` could be used in most cases in place of `for`. This is *not* true when the increment expression in the `while` follows a `continue` statement. In this case, the increment does *not* execute before the program evaluates the repetition-continuation condition, so the `while` does not execute in the same manner as the `for`.

#### Software Engineering Observation 5.4

*Some programmers feel that `break` and `continue` violate structured programming. Since the same effects are achievable with structured programming techniques, these programmers do not use `break` or `continue`.*

#### Software Engineering Observation 5.5

*There's a tension between achieving quality software engineering and achieving the best-performing software. Sometimes one of these goals is achieved at the expense of the other. For all but the most performance-intensive situations, apply the following rule of thumb: First, make your code simple and correct; then make it fast and small, but only if necessary.*

## 5.8 Logical Operators

The `if`, `if...else`, `while`, `do...while` and `for` statements each require a condition to determine how to continue a program's flow of control. So far, we've studied only simple conditions, such as `count <= 10`, `number != sentinelValue` and `total > 1000`. Simple conditions are expressed in terms of the relational operators `>`, `<`, `>=` and `<=` and the equality operators `==` and `!=`, and each expression tests only one condition. To test multiple conditions in the process of making a decision, we performed these tests in separate statements

or in nested `if` or `if...else` statements. Sometimes control statements require more complex conditions to determine a program's flow of control.

Java's **logical operators** enable you to form more complex conditions by *combining* simple conditions. The logical operators are `&&` (conditional AND), `||` (conditional OR), `&` (boolean logical AND), `|` (boolean logical inclusive OR), `^` (boolean logical exclusive OR) and `!` (logical NOT). [Note: The `&`, `|` and `^` operators are also bitwise operators when they're applied to integral operands. We discuss the bitwise operators in Appendix N.]

### Conditional AND (&&) Operator

Suppose we wish to ensure at some point in a program that two conditions are *both* true before we choose a certain path of execution. In this case, we can use the **&& (conditional AND)** operator, as follows:

```
if ( gender == FEMALE && age >= 65 )
    ++seniorFemales;
```

This `if` statement contains two simple conditions. The condition `gender == FEMALE` compares variable `gender` to the constant `FEMALE` to determine whether a person is female. The condition `age >= 65` might be evaluated to determine whether a person is a senior citizen. The `if` statement considers the combined condition

```
gender == FEMALE && age >= 65
```

which is true if and only if *both* simple conditions are true. In this case, the `if` statement's body increments `seniorFemales` by 1. If either or both of the simple conditions are false, the program skips the increment. Some programmers find that the preceding combined condition is more readable when redundant parentheses are added, as in:

```
( gender == FEMALE ) && ( age >= 65 )
```

The table in Fig. 5.14 summarizes the `&&` operator. The table shows all four possible combinations of false and true values for *expression1* and *expression2*. Such tables are called **truth tables**. Java evaluates to false or true all expressions that include relational operators, equality operators or logical operators.

expression1	expression2	expression1 && expression2
false	false	false
false	true	false
true	false	false
true	true	true

**Fig. 5.14** | `&&` (conditional AND) operator truth table.

### Conditional OR (||) Operator

Now suppose we wish to ensure that *either or both* of two conditions are true before we choose a certain path of execution. In this case, we use the **|| (conditional OR)** operator, as in the following program segment:

```
if ( semesterAverage >= 90 ) || ( finalExam >= 90 ) )
    System.out.println ( "Student grade is A" );
```

This statement also contains two simple conditions. The condition `semesterAverage >= 90` evaluates to determine whether the student deserves an A in the course because of a solid performance throughout the semester. The condition `finalExam >= 90` evaluates to determine whether the student deserves an A in the course because of an outstanding performance on the final exam. The `if` statement then considers the combined condition

```
( semesterAverage >= 90 ) || ( finalExam >= 90 )
```

and awards the student an A if *either or both* of the simple conditions are true. The only time the message "Student grade is A" is *not* printed is when *both* of the simple conditions are *false*. Figure 5.15 is a truth table for operator conditional OR (`||`). Operator `&&` has a higher precedence than operator `||`. Both operators associate from left to right.

expression1	expression2	expression1    expression2
false	false	false
false	true	true
true	false	true
true	true	true

Fig. 5.15 | `||` (conditional OR) operator truth table.

### Short-Circuit Evaluation of Complex Conditions

The parts of an expression containing `&&` or `||` operators are evaluated *only* until it's known whether the condition is true or false. Thus, evaluation of the expression

```
( gender == FEMALE ) && ( age >= 65 )
```

stops immediately if `gender` is not equal to `FEMALE` (i.e., the entire expression is `false`) and continues if `gender` *is* equal to `FEMALE` (i.e., the entire expression could still be `true` if the condition `age >= 65` is true). This feature of conditional AND and conditional OR expressions is called **short-circuit evaluation**.

### Common Programming Error 5.7

*In expressions using operator `&&`, a condition—we'll call this the dependent condition—may require another condition to be true for the evaluation of the dependent condition to be meaningful. In this case, the dependent condition should be placed after the other condition, or an error might occur. For example, in the expression `( i != 0 ) && ( 10 / i == 2 )`, the second condition must appear after the first condition, or a divide-by-zero error might occur.*

### Boolean Logical AND (&) and Boolean Logical Inclusive OR (|) Operators

The **boolean logical AND (&)** and **boolean logical inclusive OR (|)** operators are identical to the `&&` and `||` operators, except that the `&` and `|` operators *always* evaluate *both* of their operands (i.e., they do *not* perform short-circuit evaluation). So, the expression

```
( gender == 1 ) & ( age >= 65 )
```

evaluates `age >= 65` *regardless* of whether `gender` is equal to 1. This is useful if the right operand of the boolean logical AND or boolean logical inclusive OR operator has a required **side effect**—a modification of a variable's value. For example, the expression

```
( birthday == true ) | ( ++age >= 65 )
```

guarantees that the condition `++age >= 65` will be evaluated. Thus, the variable `age` is incremented, regardless of whether the overall expression is `true` or `false`.

### Error-Prevention Tip 5.6

*For clarity, avoid expressions with side effects in conditions. The side effects may seem clever, but they can make it harder to understand code and can lead to subtle logic errors.*

### Boolean Logical Exclusive OR ( $\wedge$ )

A simple condition containing the **boolean logical exclusive OR** ( $\wedge$ ) operator is true *if and only if one of its operands is true and the other is false*. If both are true or both are false, the entire condition is false. Figure 5.16 is a truth table for the boolean logical exclusive OR operator ( $\wedge$ ). This operator is guaranteed to evaluate *both* of its operands.

expression1	expression2	expression1 $\wedge$ expression2
false	false	false
false	true	true
true	false	true
true	true	false

**Fig. 5.16** |  $\wedge$  (boolean logical exclusive OR) operator truth table.

### Logical Negation (!) Operator

The **!** (**logical NOT**, also called **logical negation** or **logical complement**) operator “reverses” the meaning of a condition. Unlike the logical operators `&&`, `||`, `&`, `|` and `^`, which are *binary* operators that combine two conditions, the logical negation operator is a *unary* operator that has only a single condition as an operand. The operator is placed *before* a condition to choose a path of execution if the original condition (without the logical negation operator) is false, as in the program segment

```
if ( ! ( grade == sentinelValue ) )
    System.out.printf( "The next grade is %d\n", grade );
```

which executes the `printf` call only if `grade` is *not* equal to `sentinelValue`. The parentheses around the condition `grade == sentinelValue` are needed because the logical negation operator has a higher precedence than the equality operator.

In most cases, you can avoid using logical negation by expressing the condition differently with an appropriate relational or equality operator. For example, the previous statement may also be written as follows:

```
if ( grade != sentinelValue )
    System.out.printf( "The next grade is %d\n", grade );
```

This flexibility can help you express a condition in a more convenient manner. Figure 5.17 is a truth table for the logical negation operator.

expression	!expression
false	true
true	false

**Fig. 5.17** | ! (logical negation, or logical NOT) operator truth table.

### Logical Operators Example

Figure 5.18 uses logical operators to produce the truth tables discussed in this section. The output shows the boolean expression that was evaluated and its result. We used the **%b format specifier** to display the word “true” or the word “false” based on a boolean expression’s value. Lines 9–13 produce the truth table for `&&`. Lines 16–20 produce the truth table for `||`. Lines 23–27 produce the truth table for `&`. Lines 30–35 produce the truth table for `|`. Lines 38–43 produce the truth table for `^`. Lines 46–47 produce the truth table for `!`.

```

1 // Fig. 5.18: LogicalOperators.java
2 // Logical operators.
3
4 public class LogicalOperators
5 {
6     public static void main( String[] args )
7     {
8         // create truth table for && (conditional AND) operator
9         System.out.printf( "%s\n%s: %b\n%s: %b\n%s: %b\n%s: %b\n\n",
10             "Conditional AND (&&)", "false && false", ( false && false ),
11             "false && true", ( false && true ),
12             "true && false", ( true && false ),
13             "true && true", ( true && true ) );
14
15         // create truth table for || (conditional OR) operator
16         System.out.printf( "%s\n%s: %b\n%s: %b\n%s: %b\n%s: %b\n\n",
17             "Conditional OR (||)", "false || false", ( false || false ),
18             "false || true", ( false || true ),
19             "true || false", ( true || false ),
20             "true || true", ( true || true ) );
21
22         // create truth table for & (boolean logical AND) operator
23         System.out.printf( "%s\n%s: %b\n%s: %b\n%s: %b\n%s: %b\n\n",
24             "Boolean logical AND (&)", "false & false", ( false & false ),
25             "false & true", ( false & true ),
26             "true & false", ( true & false ),
27             "true & true", ( true & true ) );
28
29         // create truth table for | (boolean logical inclusive OR) operator
30         System.out.printf( "%s\n%s: %b\n%s: %b\n%s: %b\n%s: %b\n\n",
31             "Boolean logical inclusive OR (|)",

```

**Fig. 5.18** | Logical operators. (Part 1 of 2.)

```

32     "false | false", ( false | false ),
33     "false | true", ( false | true ),
34     "true | false", ( true | false ),
35     "true | true", ( true | true );
36
37     // create truth table for ^ (boolean logical exclusive OR) operator
38     System.out.printf( "%s\n%s: %b\n%s: %b\n%s: %b\n%s: %b\n\n",
39         "Boolean logical exclusive OR (^)",
40         "false ^ false", ( false ^ false ),
41         "false ^ true", ( false ^ true ),
42         "true ^ false", ( true ^ false ),
43         "true ^ true", ( true ^ true );
44
45     // create truth table for ! (logical negation) operator
46     System.out.printf( "%s\n%s: %b\n%s: %b\n", "Logical NOT (!)",
47         "!false", ( !false ), "!true", ( !true );
48     } // end main
49 } // end class LogicalOperators

```

```

Conditional AND (&&)
false && false: false
false && true: false
true && false: false
true && true: true

Conditional OR (||)

false || true: true
true || false: true
true || true: true

Boolean logical AND (&)
false & false: false
false & true: false
true & false: false
true & true: true

Boolean logical inclusive OR (|)
false | false: false
false | true: true
true | false: true
true | true: true

Boolean logical exclusive OR (^)
false ^ false: false
false ^ true: true
true ^ false: true
true ^ true: false

Logical NOT (!)
!false: true
!true: false

```

**Fig. 5.18** | Logical operators. (Part 2 of 2.)

Figure 5.19 shows the precedence and associativity of the Java operators introduced so far. The operators are shown from top to bottom in decreasing order of precedence.

Operators	Associativity	Type
++ --	right to left	unary postfix
++ -- + - ! (type)	right to left	unary prefix
* / %	left to right	multiplicative
+ -	left to right	additive
< <= > >=	left to right	relational
== !=	left to right	equality
&	left to right	boolean logical AND
^	left to right	boolean logical exclusive OR
	left to right	boolean logical inclusive OR
&&	left to right	conditional AND
	left to right	conditional OR
?:	right to left	conditional
= += -= *= /= %=	right to left	assignment

**Fig. 5.19** | Precedence/associativity of the operators discussed so far.

## 5.9 Structured Programming Summary

Just as architects design buildings by employing the collective wisdom of their profession, so should programmers design programs. Our field is much younger than architecture, and our collective wisdom is considerably sparser. We've learned that structured programming produces programs that are easier than unstructured programs to understand, test, debug, modify and even prove correct in a mathematical sense.

Figure 5.20 uses UML activity diagrams to summarize Java's control statements. The initial and final states indicate the *single entry point* and the *single exit point* of each control statement. Arbitrarily connecting individual symbols in an activity diagram can lead to unstructured programs. Therefore, the programming profession has chosen a limited set of control statements that can be combined in only two simple ways to build structured programs.

For simplicity, Java includes only *single-entry/single-exit* control statements—there's only one way to enter and only one way to exit each control statement. Connecting control statements in sequence to form structured programs is simple. The final state of one control statement is connected to the initial state of the next—that is, the control statements are placed one after another in a program in sequence. We call this *control-statement stacking*. The rules for forming structured programs also allow for control statements to be *nested*.

Figure 5.21 shows the rules for forming structured programs. The rules assume that action states may be used to indicate any action. The rules also assume that we begin with the simplest activity diagram (Fig. 5.22) consisting of only an initial state, an action state, a final state and transition arrows.

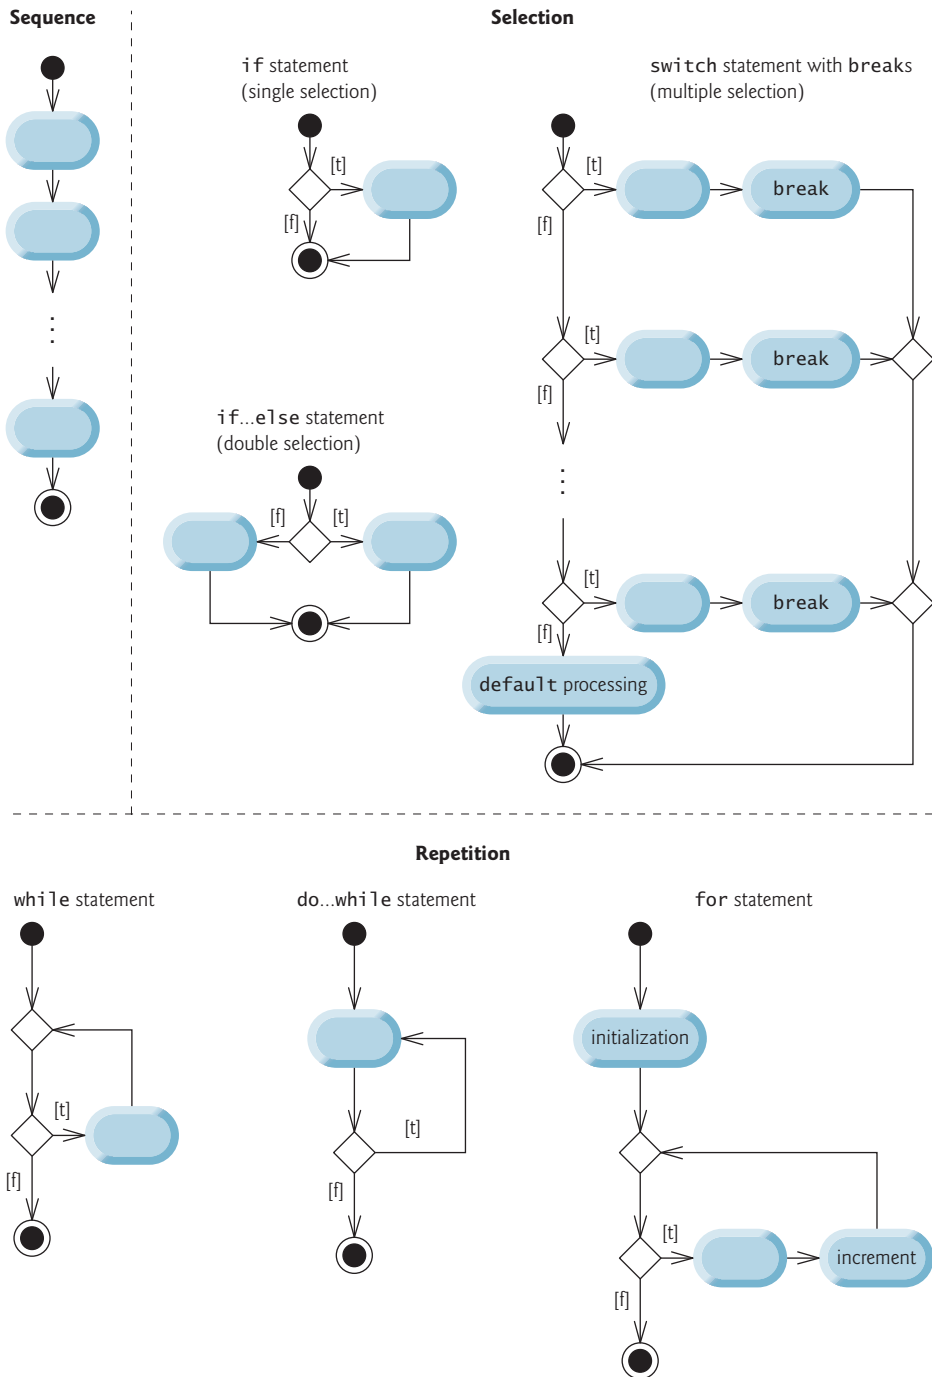

Fig. 5.20 | Java's single-entry/single-exit sequence, selection and repetition statements.

### Rules for forming structured programs

1. Begin with the simplest activity diagram (Fig. 5.22).
2. Any action state can be replaced by two action states in sequence.
3. Any action state can be replaced by any control statement (sequence of action states, if, if...else, switch, while, do...while or for).
4. Rules 2 and 3 can be applied as often as you like and in any order.

**Fig. 5.21** | Rules for forming structured programs.

Applying the rules in Fig. 5.21 always results in a properly structured activity diagram with a neat, building-block appearance. For example, repeatedly applying rule 2 to the simplest activity diagram results in an activity diagram containing many action states in sequence (Fig. 5.23). Rule 2 generates a stack of control statements, so let's call rule 2 the **stacking rule**. The vertical dashed lines in Fig. 5.23 are not part of the UML—we use them to separate the four activity diagrams that demonstrate rule 2 of Fig. 5.21 being applied.

**Fig. 5.22** | Simplest activity diagram.

**Fig. 5.23** | Repeatedly applying the Rule 2 of Fig. 5.21 to the simplest activity diagram.

Rule 3 is called the **nesting rule**. Repeatedly applying rule 3 to the simplest activity diagram results in one with neatly nested control statements. For example, in Fig. 5.24, the action state in the simplest activity diagram is replaced with a double-selection (if...else) statement. Then rule 3 is applied again to the action states in the double-selection statement, replacing each with a double-selection statement. The dashed action-state symbol around each double-selection statement represents the action state that was replaced. [Note: The dashed arrows and dashed action-state symbols shown in Fig. 5.24 are not part of the UML. They're used here to illustrate that any action state can be replaced with a control statement.]

**Fig. 5.24** | Repeatedly applying the Rule 3 of Fig. 5.21 to the simplest activity diagram.

Rule 4 generates larger, more involved and more deeply nested statements. The diagrams that emerge from applying the rules in Fig. 5.21 constitute the set of all possible structured activity diagrams and hence the set of all possible structured programs. The beauty of the structured approach is that we use *only seven* simple single-entry/single-exit control statements and assemble them in *only two* simple ways.

If the rules in Fig. 5.21 are followed, an “unstructured” activity diagram (like the one in Fig. 5.25) cannot be created. If you’re uncertain about whether a particular diagram is structured, apply the rules of Fig. 5.21 in reverse to reduce it to the simplest activity diagram. If you can reduce it, the original diagram is structured; otherwise, it’s not.

**Fig. 5.25** | “Unstructured” activity diagram.

Structured programming promotes simplicity. Only three forms of control are needed to implement an algorithm:

- Sequence
- Selection
- Repetition

The sequence structure is trivial. Simply list the statements to execute in the order in which they should execute. Selection is implemented in one of three ways:

- `if` statement (single selection)
- `if...else` statement (double selection)
- `switch` statement (multiple selection)

In fact, it’s straightforward to prove that the simple `if` statement is sufficient to provide *any* form of selection—everything that can be done with the `if...else` statement and the `switch` statement can be implemented by combining `if` statements (although perhaps not as clearly and efficiently).

Repetition is implemented in one of three ways:

- `while` statement
- `do...while` statement
- `for` statement

[*Note:* There’s a fourth repetition statement—the enhanced `for` statement—that we discuss in Section 7.6.] It’s straightforward to prove that the `while` statement is sufficient to provide *any* form of repetition. Everything that can be done with `do...while` and `for` can be done with the `while` statement (although perhaps not as conveniently).

Combining these results illustrates that *any* form of control ever needed in a Java program can be expressed in terms of

- sequence
- if statement (selection)
- while statement (repetition)

and that these can be combined in only two ways—*stacking* and *nesting*. Indeed, structured programming is the essence of simplicity.

## 5.10 (Optional) GUI and Graphics Case Study: Drawing Rectangles and Ovals

This section demonstrates drawing rectangles and ovals, using the Graphics methods `drawRect` and `drawOval`, respectively. These methods are demonstrated in Fig. 5.26.

---

```

1 // Fig. 5.26: Shapes.java
2 // Demonstrates drawing different shapes.
3 import java.awt.Graphics;
4 import javax.swing.JPanel;
5
6 public class Shapes extends JPanel
7 {
8     private int choice; // user's choice of which shape to draw
9
10    // constructor sets the user's choice
11    public Shapes( int userChoice )
12    {
13        choice = userChoice;
14    } // end Shapes constructor
15
16    // draws a cascade of shapes starting from the top-left corner
17    public void paintComponent( Graphics g )
18    {
19        super.paintComponent( g );
20
21        for ( int i = 0; i < 10; i++ )
22        {
23            // pick the shape based on the user's choice
24            switch ( choice )
25            {
26                case 1: // draw rectangles
27                    g.drawRect( 10 + i * 10, 10 + i * 10,
28                               50 + i * 10, 50 + i * 10 );
29                    break;
30                case 2: // draw ovals
31                    g.drawOval( 10 + i * 10, 10 + i * 10,
32                               50 + i * 10, 50 + i * 10 );
33                    break;
34            } // end switch
35        } // end for
36    } // end method paintComponent
37 } // end class Shapes

```

---

**Fig. 5.26** | Drawing a cascade of shapes based on the user's choice.

Line 6 begins the class declaration for `Shapes`, which extends `JPanel`. Instance variable `choice`, declared in line 8, determines whether `paintComponent` should draw rectangles or ovals. The `Shapes` constructor at lines 11–14 initializes `choice` with the value passed in parameter `userChoice`.

Method `paintComponent` (lines 17–36) performs the actual drawing. Remember, the first statement in every `paintComponent` method should be a call to `super.paintComponent`, as in line 19. Lines 21–35 loop 10 times to draw 10 shapes. The nested `switch` statement (lines 24–34) chooses between drawing rectangles and drawing ovals.

If `choice` is 1, then the program draws rectangles. Lines 27–28 call `Graphics` method `drawRect`. Method `drawRect` requires four arguments. The first two represent the  $x$ - and  $y$ -coordinates of the upper-left corner of the rectangle; the next two represent the rectangle's width and height. In this example, we start at a position 10 pixels down and 10 pixels right of the top-left corner, and every iteration of the loop moves the upper-left corner another 10 pixels down and to the right. The width and the height of the rectangle start at 50 pixels and increase by 10 pixels in each iteration.

If `choice` is 2, the program draws ovals. It creates an imaginary rectangle called a **bounding rectangle** and places inside it an oval that touches the midpoints of all four sides. Method `drawOval` (lines 31–32) requires the same four arguments as method `drawRect`. The arguments specify the position and size of the bounding rectangle for the oval. The values passed to `drawOval` in this example are exactly the same as those passed to `drawRect` in lines 27–28. Since the width and height of the bounding rectangle are identical in this example, lines 27–28 draw a circle. As an exercise, try modifying the program to draw both rectangles and ovals to see how `drawOval` and `drawRect` are related.

### Class `ShapesTest`

Figure 5.27 is responsible for handling input from the user and creating a window to display the appropriate drawing based on the user's response. Line 3 imports `JFrame` to handle the display, and line 4 imports `JOptionPane` to handle the input.

---

```

1 // Fig. 5.27: ShapesTest.java
2 // Test application that displays class Shapes.
3 import javax.swing.JFrame;
4 import javax.swing.JOptionPane;
5
6 public class ShapesTest
7 {
8     public static void main( String[] args )
9     {
10         // obtain user's choice
11         String input = JOptionPane.showInputDialog(
12             "Enter 1 to draw rectangles\n" +
13             "Enter 2 to draw ovals" );
14
15         int choice = Integer.parseInt( input ); // convert input to int
16
17         // create the panel with the user's input
18         Shapes panel = new Shapes( choice );

```

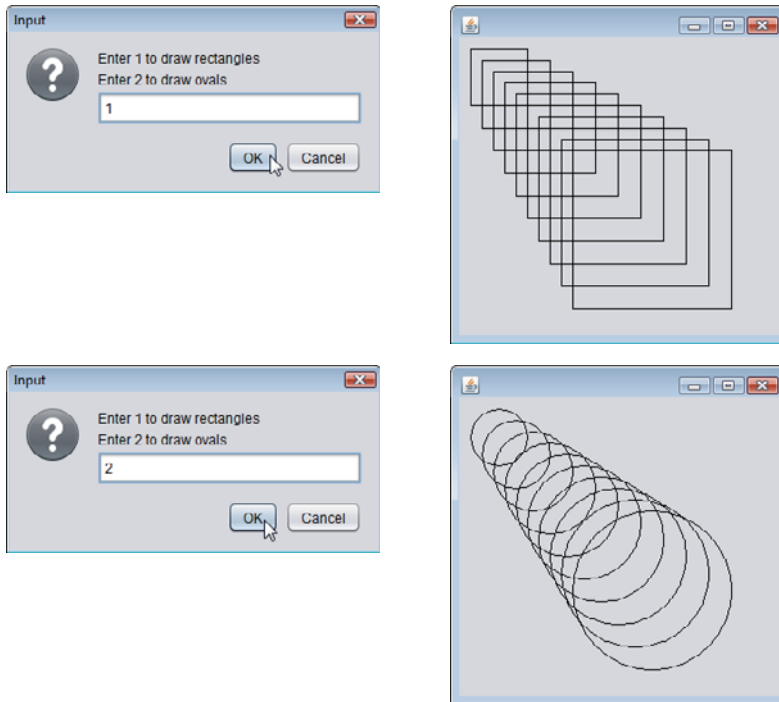

---

**Fig. 5.27** | Obtaining user input and creating a `JFrame` to display `Shapes`. (Part 1 of 2.)

```

19
20     JFrame application = new JFrame(); // creates a new JFrame
21
22     application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
23     application.add( panel ); // add the panel to the frame
24     application.setSize( 300, 300 ); // set the desired size
25     application.setVisible( true ); // show the frame
26     } // end main
27 } // end class ShapesTest

```

**Fig. 5.27** | Obtaining user input and creating a JFrame to display Shapes. (Part 2 of 2.)

Lines 11–13 prompt the user with an input dialog and store the user’s response in variable input. Line 15 uses Integer method `parseInt` to convert the String entered by the user to an `int` and stores the result in variable `choice`. Line 18 creates a `Shapes` object and passes the user’s choice to the constructor. Lines 20–25 perform the standard operations that create and set up a window in this case study—create a frame, set it to exit the application when closed, add the drawing to the frame, set the frame size and make it visible.

### *GUI and Graphics Case Study Exercises*

**5.1** Draw 12 concentric circles in the center of a `JPanel` (Fig. 5.28). The innermost circle should have a radius of 10 pixels, and each successive circle should have a radius 10 pixels larger than the previous one. Begin by finding the center of the `JPanel`. To get the upper-left corner of a circle, move up one radius and to the left one radius from the center. The width and height of the bounding rectangle are both the same as the circle’s diameter (i.e., twice the radius).

**Fig. 5.28** | Drawing concentric circles.

**5.2** Modify Exercise 5.16 from the end-of-chapter exercises to read input using dialogs and to display the bar chart using rectangles of varying lengths.

## 5.11 Wrap-Up

In this chapter, we completed our introduction to Java's control statements, which enable you to control the flow of execution in methods. Chapter 4 discussed Java's `if`, `if...else` and `while` statements. The current chapter demonstrated the `for`, `do...while` and `switch` statements. We showed that any algorithm can be developed using combinations of the sequence structure (i.e., statements listed in the order in which they should execute), the three types of selection statements—`if`, `if...else` and `switch`—and the three types of repetition statements—`while`, `do...while` and `for`. In this chapter and Chapter 4, we discussed how you can combine these building blocks to utilize proven program-construction and problem-solving techniques. This chapter also introduced Java's logical operators, which enable you to use more complex conditional expressions in control statements. In Chapter 6, we examine methods in greater depth.

## Summary

### *Section 5.2 Essentials of Counter-Controlled Repetition*

- Counter-controlled repetition (p. 152) requires a control variable, the initial value of the control variable, the increment (or decrement) by which the control variable is modified each time through the loop (also known as each iteration of the loop) and the loop-continuation condition that determines whether looping should continue.
- You can declare a variable and initialize it in the same statement.

### *Section 5.3 For Repetition Statement*

- The `while` statement can be used to implement any counter-controlled loop.
- The `for` statement (p. 154) specifies all the details of counter-controlled repetition in its header
- When the `for` statement begins executing, its control variable is declared and initialized. Next, the program checks the loop-continuation condition. If the condition is initially true, the body executes. After executing the loop's body, the increment expression executes. Then the loop-con-

tinuation test is performed again to determine whether the program should continue with the next iteration of the loop.

- The general format of the `for` statement is

```
for ( initialization; loopContinuationCondition; increment )
    statement
```

where the *initialization* expression names the loop's control variable and provides its initial value, *loopContinuationCondition* determines whether the loop should continue executing and *increment* modifies the control variable's value, so that the loop-continuation condition eventually becomes false. The two semicolons in the `for` header are required.

- Most `for` statements can be represented with equivalent `while` statements as follows:

```
initialization;
while ( loopContinuationCondition )
{
    statement
    increment;
}
```

- Typically, `for` statements are used for counter-controlled repetition and `while` statements for sentinel-controlled repetition.
- If the *initialization* expression in the `for` header declares the control variable, the control variable can be used only in that `for` statement—it will not exist outside the `for` statement.
- The expressions in a `for` header are optional. If the *loopContinuationCondition* is omitted, Java assumes that it's always true, thus creating an infinite loop. You might omit the *initialization* expression if the control variable is initialized before the loop. You might omit the *increment* expression if the increment is calculated with statements in the loop's body or if no increment is needed.
- The increment expression in a `for` acts as if it's a standalone statement at the end of the `for`'s body.
- A `for` statement can count downward by using a negative increment (i.e., a decrement).
- If the loop-continuation condition is initially `false`, the program does not execute the `for` statement's body. Instead, execution proceeds with the statement following the `for`.

### Section 5.4 Examples Using the `for` Statement

- Java treats floating-point constants like `1000.0` and `0.05` as type `double`. Similarly, Java treats whole-number constants like `7` and `-22` as type `int`.
- The format specifier `%4s` outputs a `String` in a field width (p. 160) of 4—that is, `printf` displays the value with at least 4 character positions. If the value to be output is less than 4 character positions wide, the value is right justified (p. 160) in the field by default. If the value is greater than 4 character positions wide, the field width expands to accommodate the appropriate number of characters. To left justify (p. 160) the value, use a negative integer to specify the field width.
- `Math.pow(x, y)` (p. 161) calculates the value of  $x$  raised to the  $y^{\text{th}}$  power. The method receives two `double` arguments and returns a `double` value.
- The comma (,) formatting flag (p. 161) in a format specifier indicates that a floating-point value should be output with a grouping separator (p. 161). The actual separator used is specific to the user's locale (i.e., country). In the United States, the number will have commas separating every three digits and a decimal point separating the fractional part of the number, as in `1,234.45`.
- The `.` in a format specifier indicates that the integer to its right is the number's precision.

### Section 5.5 `do...while` Repetition Statement

- The `do...while` statement (p. 162) is similar to the `while` statement. In the `while`, the program tests the loop-continuation condition at the beginning of the loop, before executing its body; if the con-

dition is false, the body never executes. The `do...while` statement tests the loop-continuation condition *after* executing the loop's body; therefore, the body always executes at least once.

### Section 5.6 *switch Multiple-Selection Statement*

- The `switch` statement (p. 164) performs different actions based on the possible values of a constant integral expression (a constant value of type `byte`, `short`, `int` or `char`, but not `long`).
- The end-of-file indicator (p. 167) is a system-dependent keystroke combination that terminates user input. On UNIX/Linux/Mac OS X systems, end-of-file is entered by typing the sequence `<Ctrl> d` on a line by itself. This notation means to simultaneously press both the `Ctrl` key and the `d` key. On Windows systems, enter end-of-file by typing `<Ctrl> z`.
- Scanner method `hasNext` (p. 167) determines whether there's more data to input. This method returns the `boolean` value `true` if there's more data; otherwise, it returns `false`. As long as the end-of-file indicator has not been typed, method `hasNext` will return `true`.
- The `switch` statement consists of a block that contains a sequence of case labels (p. 168) and an optional `default` case (p. 168).
- When the flow of control reaches a `switch`, the program evaluates the `switch`'s controlling expression and compares its value with each case label. If a match occurs, the program executes the statements for that case.
- Listing cases consecutively with no statements between them enables the cases to perform the same set of statements.
- Every value you wish to test in a `switch` must be listed in a separate case label.
- Each case can have multiple statements, and these need not be placed in braces.
- Without `break` statements, each time a match occurs in the `switch`, the statements for that case and subsequent cases execute until a `break` statement or the end of the `switch` is encountered.
- If no match occurs between the controlling expression's value and a case label, the optional `default` case executes. If no match occurs and the `switch` does not contain a `default` case, program control simply continues with the first statement after the `switch`.
- As of Java SE 7, you can use `Strings` in a `switch` statement's controlling expression and case labels.

### Section 5.7 *break and continue Statements*

- The `break` statement (p. 168), when executed in a `while`, `for`, `do...while` or `switch`, causes immediate exit from that statement.
- The `continue` statement (p. 172), when executed in a `while`, `for` or `do...while`, skips the loop's remaining body statements and proceeds with its next iteration. In `while` and `do...while` statements, the program evaluates the loop-continuation test immediately. In a `for` statement, the increment expression executes, then the program evaluates the loop-continuation test.

### Section 5.8 *Logical Operators*

- Simple conditions are expressed in terms of the relational operators `>`, `<`, `>=` and `<=` and the equality operators `==` and `!=`, and each expression tests only one condition.
- Logical operators (p. 174) enable you to form more complex conditions by combining simple conditions. The logical operators are `&&` (conditional AND), `||` (conditional OR), `&` (boolean logical AND), `|` (boolean logical inclusive OR), `^` (boolean logical exclusive OR) and `!` (logical NOT).
- To ensure that two conditions are *both* true, use the `&&` (conditional AND) operator. If either or both of the simple conditions are false, the entire expression is false.
- To ensure that either *or* both of two conditions are true, use the `||` (conditional OR) operator, which evaluates to true if either or both of its simple conditions are true.

- A condition using `&&` or `||` operators (p. 174) uses short-circuit evaluation (p. 175)—they’re evaluated only until it’s known whether the condition is true or false.
- The `&` and `|` operators (p. 175) work identically to the `&&` and `||` operators, but always evaluate both operands.
- A simple condition containing the boolean logical exclusive OR (`^`; p. 176) operator is true *if and only if one of its operands is true and the other is false*. If both operands are true or both are false, the entire condition is false. This operator is also guaranteed to evaluate both of its operands.
- The unary `!` (logical NOT; p. 176) operator “reverses” the value of a condition.

## Self-Review Exercises

**5.1** (*Fill in the Blanks*) Fill in the blanks in each of the following statements:

- Typically, \_\_\_\_\_ statements are used for counter-controlled repetition and \_\_\_\_\_ statements for sentinel-controlled repetition.
- The `do...while` statement tests the loop-continuation condition \_\_\_\_\_ executing the loop’s body; therefore, the body always executes at least once.
- The \_\_\_\_\_ statement selects among multiple actions based on the possible values of an integer variable or expression.
- The \_\_\_\_\_ statement, when executed in a repetition statement, skips the remaining statements in the loop body and proceeds with the next iteration of the loop.
- The \_\_\_\_\_ operator can be used to ensure that two conditions are *both* true before choosing a certain path of execution.
- If the loop-continuation condition in a `for` header is initially \_\_\_\_\_, the program does not execute the `for` statement’s body.
- Methods that perform common tasks and do not require objects are called \_\_\_\_\_ methods.

**5.2** (*True/False Questions*) State whether each of the following is *true* or *false*. If *false*, explain why.

- The `default` case is required in the `switch` selection statement.
- The `break` statement is required in the last case of a `switch` selection statement.
- The expression `(( x > y ) && ( a < b ) )` is true if either `x > y` is true or `a < b` is true.
- An expression containing the `||` operator is true if either or both of its operands are true.
- The comma `,` formatting flag in a format specifier (e.g., `%, 20.2f`) indicates that a value should be output with a thousands separator.
- To test for a range of values in a `switch` statement, use a hyphen `-` between the start and end values of the range in a case label.
- Listing cases consecutively with no statements between them enables the cases to perform the same set of statements.

**5.3** (*Write a Statement*) Write a Java statement or a set of Java statements to accomplish each of the following tasks:

- Sum the odd integers between 1 and 99, using a `for` statement. Assume that the integer variables `sum` and `count` have been declared.
- Calculate the value of 2.5 raised to the power of 3, using the `pow` method.
- Print the integers from 1 to 20, using a `while` loop and the counter variable `i`. Assume that the variable `i` has been declared, but not initialized. Print only five integers per line. [*Hint: Use the calculation `i % 5`. When the value of this expression is 0, print a newline character; otherwise, print a tab character. Assume that this code is an application. Use the `System.out.println()` method to output the newline character, and use the `System.out.print( '\t' )` method to output the tab character.]*
- Repeat part (c), using a `for` statement.

**5.4** (*Find the Error*) Find the error in each of the following code segments, and explain how to correct it:

- a) `i = 1;`
- ```

while ( i <= 10 );
    ++i;
}

```
- b) `for ( k = 0.1; k != 1.0; k += 0.1 )`  
`System.out.println( k );`
- c) `switch ( n )`  
`{`  
`case 1:`  
`System.out.println( "The number is 1" );`  
`case 2:`  
`System.out.println( "The number is 2" );`  
`break;`  
`default:`  
`System.out.println( "The number is not 1 or 2" );`  
`break;`  
`}`
- d) The following code should print the values 1 to 10:  
`n = 1;`  
`while ( n < 10 )`  
`System.out.println( n++ );`

## Answers to Self-Review Exercises

**5.1** a) for, while. b) after. c) switch. d) continue. e) && (conditional AND). f) false. g) static.

**5.2** a) False. The default case is optional. If no default action is needed, then there's no need for a default case. b) False. The break statement is used to exit the switch statement. The break statement is not required for the last case in a switch statement. c) False. Both of the relational expressions must be true for the entire expression to be true when using the && operator. d) True. e) True. f) False. The switch statement does not provide a mechanism for testing ranges of values, so every value that must be tested should be listed in a separate case label. g) True.

- 5.3** a) `sum = 0;`  
`for ( count = 1; count <= 99; count += 2 )`  
`sum += count;`
- b) `double result = Math.pow( 2.5, 3 );`
- c) `i = 1;`
- ```

while ( i <= 20 )
{
    System.out.print( i );

    if ( i % 5 == 0 )
        System.out.println();
    else
        System.out.print( '\t' );

    ++i;
}

```
- f) `for ( i = 1; i <= 20; i++ )`  
`{`  
`System.out.print( i );`

```

    if ( i % 5 == 0 )
        System.out.println();
    else
        System.out.print( '\t' );
}

```

- 5.4** a) Error: The semicolon after the `while` header causes an infinite loop, and there's a missing left brace.  
Correction: Replace the semicolon by a `{`, or remove both the `;` and the `}`.
- b) Error: Using a floating-point number to control a `for` statement may not work, because floating-point numbers are represented only approximately by most computers.  
Correction: Use an integer, and perform the proper calculation in order to get the values you desire:

```

    for ( k = 1; k != 10; k++ )
        System.out.println( (double) k / 10 );

```

- c) Error: The missing code is the `break` statement in the statements for the first case.  
Correction: Add a `break` statement at the end of the statements for the first case. This omission is not necessarily an error if you want the statement of case 2: to execute every time the case 1: statement executes.
- d) Error: An improper relational operator is used in the `while`'s continuation condition.  
Correction: Use `<=` rather than `<`, or change 10 to 11.

## Exercises

- 5.5** Describe the four basic elements of counter-controlled repetition.
- 5.6** Compare and contrast the `while` and `for` repetition statements.
- 5.7** Discuss a situation in which it would be more appropriate to use a `do...while` statement than a `while` statement. Explain why.
- 5.8** Compare and contrast the `break` and `continue` statements.
- 5.9** Find and correct the error(s) in each of the following segments of code:
- a) `For ( i = 100, i >= 1, i++ )`  
`System.out.println( i );`
- b) The following code should print whether integer value is odd or even:

```

    switch ( value % 2 )
    {
        case 0:
            System.out.println( "Even integer" );
        case 1:
            System.out.println( "Odd integer" );
    }

```

- c) The following code should output the odd integers from 19 to 1:
- ```

    for ( i = 19; i >= 1; i += 2 )
        System.out.println( i );

```
- d) The following code should output the even integers from 2 to 100:

```

    counter = 2;
    do
    {
        System.out.println( counter );
        counter += 2;
    } While ( counter < 100 );

```

5.10 What does the following program do?

```

1 // Exercise 5.10: Printing.java
2 public class Printing
3 {
4     public static void main( String[] args )
5     {
6         for ( int i = 1; i <= 10; i++ )
7         {
8             for ( int j = 1; j <= 5; j++ )
9                 System.out.print( '@' );
10
11             System.out.println();
12         } // end outer for
13     } // end main
14 } // end class Printing

```

5.11 (*Find the Smallest Value*) Write an application that finds the smallest of several integers. Assume that the first value read specifies the number of values to input from the user.

5.12 (*Calculating the Product of Odd Integers*) Write an application that calculates the product of the odd integers from 1 to 15.

5.13 (*Factorials*) Factorials are used frequently in probability problems. The factorial of a positive integer  $n$  (written  $n!$  and pronounced “ $n$  factorial”) is equal to the product of the positive integers from 1 to  $n$ . Write an application that calculates the factorials of 1 through 20. Use type `long`. Display the results in tabular format. What difficulty might prevent you from calculating the factorial of 100?

5.14 (*Modified Compound-Interest Program*) Modify the compound-interest application of Fig. 5.6 to repeat its steps for interest rates of 5%, 6%, 7%, 8%, 9% and 10%. Use a `for` loop to vary the interest rate.

5.15 (*Triangle Printing Program*) Write an application that displays the following patterns separately, one below the other. Use `for` loops to generate the patterns. All asterisks (\*) should be printed by a single statement of the form `System.out.print( '*' );` which causes the asterisks to print side by side. A statement of the form `System.out.println();` can be used to move to the next line. A statement of the form `System.out.print( ' ' );` can be used to display a space for the last two patterns. There should be no other output statements in the program. [*Hint*: The last two patterns require that each line begin with an appropriate number of blank spaces.]

| (a)   | (b)   | (c)   | (d)   |
|-------|-------|-------|-------|
| *     | ***** | ***** | *     |
| **    | ***** | ***** | **    |
| ***   | ***** | ***** | ***   |
| ****  | ***** | ***** | ****  |
| ***** | ***** | ***** | ***** |
| ***** | ***** | ***** | ***** |
| ***** | ***** | ***** | ***** |
| ***** | ***   | ***   | ***** |
| ***** | **    | **    | ***** |
| ***** | *     | *     | ***** |

5.16 (*Bar Chart Printing Program*) One interesting application of computers is to display graphs and bar charts. Write an application that reads five numbers between 1 and 30. For each number that’s read, your program should display the same number of adjacent asterisks. For example, if your program reads the number 7, it should display `*****`. Display the bars of asterisks *after* you read all five numbers.

**5.17** (*Calculating Sales*) An online retailer sells five products whose retail prices are as follows: Product 1, \$2.98; product 2, \$4.50; product 3, \$9.98; product 4, \$4.49 and product 5, \$6.87. Write an application that reads a series of pairs of numbers as follows:

- a) product number
- b) quantity sold

Your program should use a switch statement to determine the retail price for each product. It should calculate and display the total retail value of all products sold. Use a sentinel-controlled loop to determine when the program should stop looping and display the final results.

**5.18** (*Modified Compound-Interest Program*) Modify the application in Fig. 5.6 to use only integers to calculate the compound interest. [*Hint*: Treat all monetary amounts as integral numbers of pennies. Then break the result into its dollars and cents portions by using the division and remainder operations, respectively. Insert a period between the dollars and the cents portions.]

**5.19** Assume that  $i = 1$ ,  $j = 2$ ,  $k = 3$  and  $m = 2$ . What does each of the following statements print?

- a) `System.out.println( i == 1 );`
- b) `System.out.println( j == 3 );`
- c) `System.out.println( ( i >= 1 ) && ( j < 4 ) );`
- d) `System.out.println( ( m <= 99 ) & ( k < m ) );`
- e) `System.out.println( ( j >= i ) || ( k == m ) );`
- f) `System.out.println( ( k + m < j ) | ( 3 - j >= k ) );`
- g) `System.out.println( !( k > m ) );`

**5.20** (*Calculating the Value of  $\pi$* ) Calculate the value of  $\pi$  from the infinite series

$$\pi = 4 - \frac{4}{3} + \frac{4}{5} - \frac{4}{7} + \frac{4}{9} - \frac{4}{11} + \dots$$

Print a table that shows the value of  $\pi$  approximated by computing the first 200,000 terms of this series. How many terms do you have to use before you first get a value that begins with 3.14159?

**5.21** (*Pythagorean Triples*) A right triangle can have sides whose lengths are all integers. The set of three integer values for the lengths of the sides of a right triangle is called a Pythagorean triple. The lengths of the three sides must satisfy the relationship that the sum of the squares of two of the sides is equal to the square of the hypotenuse. Write an application that displays a table of the Pythagorean triples for `side1`, `side2` and the hypotenuse, all no larger than 500. Use a triple-nested for loop that tries all possibilities. This method is an example of “brute-force” computing. You’ll learn in more advanced computer science courses that for many interesting problems there’s no known algorithmic approach other than using sheer brute force.

**5.22** (*Modified Triangle Printing Program*) Modify Exercise 5.15 to combine your code from the four separate triangles of asterisks such that all four patterns print side by side. [*Hint*: Make clever use of nested for loops.]

**5.23** (*De Morgan’s Laws*) In this chapter, we discussed the logical operators `&&`, `&`, `||`, `|`, `^` and `!`. De Morgan’s laws can sometimes make it more convenient for us to express a logical expression. These laws state that the expression `!(condition1 && condition2)` is logically equivalent to the expression `!(condition1 || !condition2)`. Also, the expression `!(condition1 || condition2)` is logically equivalent to the expression `!(condition1 && !condition2)`. Use De Morgan’s laws to write equivalent expressions for each of the following, then write an application to show that both the original expression and the new expression in each case produce the same value:

- a) `!( x < 5 ) && !( y >= 7 )`
- b) `!( a == b ) || !( g != 5 )`
- c) `!( ( x <= 8 ) && ( y > 4 ) )`
- d) `!( ( i > 4 ) || ( j <= 6 ) )`

**5.24** (*Diamond Printing Program*) Write an application that prints the following diamond shape. You may use output statements that print a single asterisk (\*), a single space or a single new-line character. Maximize your use of repetition (with nested for statements), and minimize the number of output statements.

```

    *
   ***
  *****
 *****
*****
 *****
  *****
   ***
    *
```

**5.25** (*Modified Diamond Printing Program*) Modify the application you wrote in Exercise 5.24 to read an odd number in the range 1 to 19 to specify the number of rows in the diamond. Your program should then display a diamond of the appropriate size.

**5.26** A criticism of the `break` statement and the `continue` statement is that each is unstructured. Actually, these statements can always be replaced by structured statements, although doing so can be awkward. Describe in general how you'd remove any `break` statement from a loop in a program and replace it with some structured equivalent. [*Hint*: The `break` statement exits a loop from the body of the loop. The other way to exit is by failing the loop-continuation test. Consider using in the loop-continuation test a second test that indicates “early exit because of a ‘break’ condition.”] Use the technique you develop here to remove the `break` statement from the application in Fig. 5.12.

**5.27** What does the following program segment do?

```

for ( i = 1; i <= 5; i++ )
{
    for ( j = 1; j <= 3; j++ )
    {
        for ( k = 1; k <= 4; k++ )
            System.out.print( '*' );

        System.out.println();
    } // end inner for
    System.out.println();
} // end outer for
```

**5.28** Describe in general how you'd remove any `continue` statement from a loop in a program and replace it with some structured equivalent. Use the technique you develop here to remove the `continue` statement from the program in Fig. 5.13.

**5.29** (*“The Twelve Days of Christmas” Song*) Write an application that uses repetition and `switch` statements to print the song “The Twelve Days of Christmas.” One `switch` statement should be used to print the day (“first,” “second,” and so on). A separate `switch` statement should be used to print the remainder of each verse. Visit the website [en.wikipedia.org/wiki/The\\_Twelve\\_Days\\_of\\_Christmas\\_\(song\)](http://en.wikipedia.org/wiki/The_Twelve_Days_of_Christmas_(song)) for the lyrics of the song.

## Making a Difference

**5.30** (*Global Warming Facts Quiz*) The controversial issue of global warming has been widely publicized by the film “An Inconvenient Truth,” featuring former Vice President Al Gore. Mr. Gore and a U.N. network of scientists, the Intergovernmental Panel on Climate Change, shared the 2007 Nobel Peace Prize in recognition of “their efforts to build up and disseminate greater knowledge about man-made climate change.” Research *both* sides of the global warming issue online (you

might want to search for phrases like “global warming skeptics”). Create a five-question multiple-choice quiz on global warming, each question having four possible answers (numbered 1–4). Be objective and try to fairly represent both sides of the issue. Next, write an application that administers the quiz, calculates the number of correct answers (zero through five) and returns a message to the user. If the user correctly answers five questions, print “Excellent”; if four, print “Very good”; if three or fewer, print “Time to brush up on your knowledge of global warming,” and include a list of some of the websites where you found your facts.

**5.31** (*Tax Plan Alternatives; The “FairTax”*) There are many proposals to make taxation fairer. Check out the FairTax initiative in the United States at

[www.fairtax.org/site/PageSer PageServer?pagename=calculator](http://www.fairtax.org/site/PageSer PageServer?pagename=calculator)

Research how the proposed FairTax works. One suggestion is to eliminate income taxes and most other taxes in favor of a 23% consumption tax on all products and services that you buy. Some FairTax opponents question the 23% figure and say that because of the way the tax is calculated, it would be more accurate to say the rate is 30%—check this carefully. Write a program that prompts the user to enter expenses in various expense categories they have (e.g., housing, food, clothing, transportation, education, health care, vacations), then prints the estimated FairTax that person would pay.

**5.32** (*Facebook User Base Growth*) According to CNNMoney.com, Facebook hit 500 million users in July of 2010 and its user base has been growing at a rate of 5% per month. Using the compound-growth technique you learned in Fig. 5.6 and assuming this growth rate continues, how many months will it take for Facebook to grow its user base to one billion users? How many months will it take for Facebook to grow its user base to two billion users (which, at the time of this writing, was the total number of people on the Internet)?

## Objectives

In this chapter you'll learn:

- How **static** methods and fields are associated with classes rather than objects.
- How the method call/return mechanism is supported by the method-call stack.
- How packages group related classes.
- How to use random-number generation to implement game-playing applications.
- How the visibility of declarations is limited to specific regions of programs.
- What method overloading is and how to create overloaded methods.

- 6.1 Introduction
- 6.2 Program Modules in Java
- 6.3 `static` Methods, `static` Fields and Class `Math`
- 6.4 Declaring Methods with Multiple Parameters
- 6.5 Notes on Declaring and Using Methods
- 6.6 Method-Call Stack and Activation Records
- 6.7 Argument Promotion and Casting
- 6.8 Java API Packages
- 6.9 Case Study: Random-Number Generation
  - 6.9.1 Generalized Scaling and Shifting of Random Numbers
  - 6.9.2 Random-Number Repeatability for Testing and Debugging
- 6.10 Case Study: A Game of Chance; Introducing Enumerations
- 6.11 Scope of Declarations
- 6.12 Method Overloading
- 6.13 (Optional) GUI and Graphics Case Study: Colors and Filled Shapes
- 6.14 Wrap-Up

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference*

## 6.1 Introduction

Experience has shown that the best way to develop and maintain a large program is to construct it from small, simple pieces, or **modules**. This technique is called **divide and conquer**. Methods, which we introduced in Chapter 3, help you modularize programs. In this chapter, we study methods in more depth. We emphasize how to declare and use methods to facilitate the design, implementation, operation and maintenance of large programs.

You'll see that it's possible to call certain methods, called `static` methods, without the need for an object of the class to exist. You'll learn how to declare a method with more than one parameter. You'll also learn how Java is able to keep track of which method is currently executing, how local variables of methods are maintained in memory and how a method knows where to return after it completes execution.

We'll take a brief diversion into simulation techniques with random-number generation and develop a version of the casino dice game called craps that uses most of the programming techniques you've used to this point in the book. In addition, you'll learn how to declare values that cannot change (i.e., constants) in your programs.

Many of the classes you'll use or create while developing applications will have more than one method of the same name. This technique, called overloading, is used to implement methods that perform similar tasks for arguments of different types or for different numbers of arguments.

We continue our discussion of methods in Chapter 18, Recursion. Recursion provides an intriguing way of thinking about methods and algorithms.

## 6.2 Program Modules in Java

You write Java programs by combining new methods and classes with predefined ones available in the **Java Application Programming Interface** (also referred to as the **Java API** or **Java class library**) and in various other class libraries. Related classes are typically grouped into packages so that they can be imported into programs and reused. You'll learn

how to group your own classes into packages in Chapter 8. The Java API provides a rich collection of predefined classes that contain methods for performing common mathematical calculations, string manipulations, character manipulations, input/output operations, database operations, networking operations, file processing, error checking and many other useful tasks.

### Software Engineering Observation 6.1

*Familiarize yourself with the rich collection of classes and methods provided by the Java API ([download.oracle.com/javase/6/docs/api/](http://download.oracle.com/javase/6/docs/api/)). Section 6.8 presents an overview of several common packages. Appendix E explains how to navigate the API documentation. Don't reinvent the wheel. When possible, reuse Java API classes and methods. This reduces program development time and avoids introducing programming errors.*

Methods (called **functions** or **procedures** in some languages) help you modularize a program by separating its tasks into self-contained units. You've declared methods in every program you've written. The statements in the method bodies are written only once, are hidden from other methods and can be reused from several locations in a program.

One motivation for modularizing a program into methods is the divide-and-conquer approach, which makes program development more manageable by constructing programs from small, simple pieces. Another is **software reusability**—using existing methods as building blocks to create new programs. Often, you can create programs mostly from standardized methods rather than by building customized code. For example, in earlier programs, we did not define how to read data from the keyboard—Java provides these capabilities in the methods of class `Scanner`. A third motivation is to avoid repeating code. Dividing a program into meaningful methods makes the program easier to debug and maintain.

### Software Engineering Observation 6.2

*To promote software reusability, every method should be limited to performing a single, well-defined task, and the name of the method should express that task effectively.*

### Error-Prevention Tip 6.1

*A method that performs one task is easier to test and debug than one that performs many tasks.*

### Software Engineering Observation 6.3

*If you cannot choose a concise name that expresses a method's task, your method might be attempting to perform too many tasks. Break such a method into several smaller ones.*

As you know, a method is invoked by a method call, and when the called method completes its task, it returns either a result or simply control to the caller. An analogy to this program structure is the hierarchical form of management (Fig. 6.1). A boss (the caller) asks a worker (the called method) to perform a task and report back (return) the results after completing the task. The boss method does not know how the worker method performs its designated tasks. The worker may also call other worker methods, unknown to the boss. This “hiding” of implementation details promotes good software engineering. Figure 6.1 shows the boss method communicating with several worker methods in a hierarchical manner. The boss method divides its responsibilities among the various worker methods. Here, `worker1` acts as a “boss method” to `worker4` and `worker5`.

**Fig. 6.1** | Hierarchical boss-method/worker-method relationship.

### 6.3 static Methods, static Fields and Class Math

Although most methods execute in response to method calls on specific objects, this is not always the case. Sometimes a method performs a task that does not depend on the contents of any object. Such a method applies to the class in which it's declared as a whole and is known as a **static method** or a **class method**. It's common for classes to contain convenient static methods to perform common tasks. For example, recall that we used static method `pow` of class `Math` to raise a value to a power in Fig. 5.6. To declare a method as `static`, place the keyword `static` before the return type in the method's declaration. For any class imported into your program, you can call the class's static methods by specifying the name of the class in which the method is declared, followed by a dot (`.`) and the method name, as in

```
ClassName.methodName( arguments )
```

We use various `Math` class methods here to present the concept of static methods. Class `Math` provides a collection of methods that enable you to perform common mathematical calculations. For example, you can calculate the square root of `900.0` with the static method call

```
Math.sqrt( 900.0 )
```

The preceding expression evaluates to `30.0`. Method `sqrt` takes an argument of type `double` and returns a result of type `double`. To output the value of the preceding method call in the command window, you might write the statement

```
System.out.println( Math.sqrt( 900.0 ) );
```

In this statement, the value that `sqrt` returns becomes the argument to method `println`. There was no need to create a `Math` object before calling method `sqrt`. Also *all* `Math` class methods are `static`—therefore, each is called by preceding its name with the class name `Math` and the dot (`.`) separator.

#### Software Engineering Observation 6.4

*Class `Math` is part of the `java.lang` package, which is implicitly imported by the compiler, so it's not necessary to import class `Math` to use its methods.*

Method arguments may be constants, variables or expressions. If `c = 13.0`, `d = 3.0` and `f = 4.0`, then the statement

```
System.out.println( Math.sqrt( c + d * f ) );
```

calculates and prints the square root of  $13.0 + 3.0 * 4.0 = 25.0$ —namely, 5.0. Figure 6.2 summarizes several Math class methods. In the figure,  $x$  and  $y$  are of type double.

| Method                   | Description                                            | Example                                                                                                 |
|--------------------------|--------------------------------------------------------|---------------------------------------------------------------------------------------------------------|
| <code>abs( x )</code>    | absolute value of $x$                                  | <code>abs( 23.7 )</code> is 23.7<br><code>abs( 0.0 )</code> is 0.0<br><code>abs( -23.7 )</code> is 23.7 |
| <code>ceil( x )</code>   | rounds $x$ to the smallest integer not less than $x$   | <code>ceil( 9.2 )</code> is 10.0<br><code>ceil( -9.8 )</code> is -9.0                                   |
| <code>cos( x )</code>    | trigonometric cosine of $x$ ( $x$ in radians)          | <code>cos( 0.0 )</code> is 1.0                                                                          |
| <code>exp( x )</code>    | exponential method $e^x$                               | <code>exp( 1.0 )</code> is 2.71828<br><code>exp( 2.0 )</code> is 7.38906                                |
| <code>floor( x )</code>  | rounds $x$ to the largest integer not greater than $x$ | <code>floor( 9.2 )</code> is 9.0<br><code>floor( -9.8 )</code> is -10.0                                 |
| <code>log( x )</code>    | natural logarithm of $x$ (base $e$ )                   | <code>log( Math.E )</code> is 1.0<br><code>log( Math.E * Math.E )</code> is 2.0                         |
| <code>max( x, y )</code> | larger value of $x$ and $y$                            | <code>max( 2.3, 12.7 )</code> is 12.7<br><code>max( -2.3, -12.7 )</code> is -2.3                        |
| <code>min( x, y )</code> | smaller value of $x$ and $y$                           | <code>min( 2.3, 12.7 )</code> is 2.3<br><code>min( -2.3, -12.7 )</code> is -12.7                        |
| <code>pow( x, y )</code> | $x$ raised to the power $y$ (i.e., $x^y$ )             | <code>pow( 2.0, 7.0 )</code> is 128.0<br><code>pow( 9.0, 0.5 )</code> is 3.0                            |
| <code>sin( x )</code>    | trigonometric sine of $x$ ( $x$ in radians)            | <code>sin( 0.0 )</code> is 0.0                                                                          |
| <code>sqrt( x )</code>   | square root of $x$                                     | <code>sqrt( 900.0 )</code> is 30.0                                                                      |
| <code>tan( x )</code>    | trigonometric tangent of $x$ ( $x$ in radians)         | <code>tan( 0.0 )</code> is 0.0                                                                          |

**Fig. 6.2** | Math class methods.

### Math Class Constants PI and E

Class Math declares two fields that represent commonly used mathematical constants—**Math.PI** and **Math.E**. **Math.PI** (3.141592653589793) is the ratio of a circle's circumference to its diameter. **Math.E** (2.718281828459045) is the base value for natural logarithms (calculated with `static Math` method `log`). These fields are declared in class Math with the modifiers `public`, `final` and `static`. Making them `public` allows you to use these fields in your own classes. Any field declared with keyword **final** is constant—its value cannot change after the field is initialized. **PI** and **E** are declared `final` because their values never change. Making these fields `static` allows them to be accessed via the class name Math and a dot (.) separator, just like class Math's methods. Recall from Section 3.4 that when each object of a class maintains its own copy of an attribute, the field that represents the attribute is also known as an instance variable—each object (instance) of the class has a separate instance of the variable in memory. There are fields for which each object of a class does *not* have a separate instance of the field. That's the case with `static` fields, which are also known as **class variables**. When objects of a class containing `static` fields are created, all

the objects of that class share one copy of the class's static fields. Together the class variables (i.e., static variables) and instance variables represent the fields of a class. You'll learn more about static fields in Section 8.11.

### Why Is Method `main` Declared `static`?

When you execute the Java Virtual Machine (JVM) with the `java` command, the JVM attempts to invoke the `main` method of the class you specify—when no objects of the class have been created. Declaring `main` as `static` allows the JVM to invoke `main` without creating an instance of the class. When you execute your application, you specify its class name as an argument to the command `java`, as in

```
java ClassName argument1 argument2 ...
```

The JVM loads the class specified by `ClassName` and uses that class name to invoke method `main`. In the preceding command, `ClassName` is a **command-line argument** to the JVM that tells it which class to execute. Following the `ClassName`, you can also specify a list of `Strings` (separated by spaces) as command-line arguments that the JVM will pass to your application. Such arguments might be used to specify options (e.g., a file name) to run the application. As you'll learn in Chapter 7, `Arrays` and `ArrayLists`, your application can access those command-line arguments and use them to customize the application.

## 6.4 Declaring Methods with Multiple Parameters

Methods often require more than one piece of information to perform their tasks. We now consider how to write your own methods with multiple parameters.

Figure 6.3 uses a method called `maximum` to determine and return the largest of three `double` values. In `main`, lines 14–18 prompt the user to enter three `double` values, then read them from the user. Line 21 calls method `maximum` (declared in lines 28–41) to determine the largest of the three values it receives as arguments. When method `maximum` returns the result to line 21, the program assigns `maximum`'s return value to local variable `result`. Then line 24 outputs the maximum value. At the end of this section, we'll discuss the use of operator `+` in line 24.

---

```

1 // Fig. 6.3: MaximumFinder.java
2 // Programmer-declared method maximum with three double parameters.
3 import java.util.Scanner;
4
5 public class MaximumFinder
6 {
7     // obtain three floating-point values and locate the maximum value
8     public static void main( String[] args )
9     {
10        // create Scanner for input from command window
11        Scanner input = new Scanner( System.in );
12
13        // prompt for and input three floating-point values
14        System.out.print(
15            "Enter three floating-point values separated by spaces: " );

```

---

**Fig. 6.3** | Programmer-declared method `maximum` with three `double` parameters. (Part 1 of 2.)

```
16     double number1 = input.nextDouble(); // read first double
17     double number2 = input.nextDouble(); // read second double
18     double number3 = input.nextDouble(); // read third double
19
20     // determine the maximum value
21     double result = maximum( number1, number2, number3 );
22
23     // display maximum value
24     System.out.println( "Maximum is: " + result );
25 } // end main
26
27 // returns the maximum of its three double parameters
28 public static double maximum( double x, double y, double z )
29 {
30     double maximumValue = x; // assume x is the largest to start
31
32     // determine whether y is greater than maximumValue
33     if ( y > maximumValue )
34         maximumValue = y;
35
36     // determine whether z is greater than maximumValue
37     if ( z > maximumValue )
38         maximumValue = z;
39
40     return maximumValue;
41 } // end method maximum
42 } // end class MaximumFinder
```

```
Enter three floating-point values separated by spaces: 9.35 2.74 5.1
Maximum is: 9.35
```

```
Enter three floating-point values separated by spaces: 5.8 12.45 8.32
Maximum is: 12.45
```

```
Enter three floating-point values separated by spaces: 6.46 4.12 10.54
Maximum is: 10.54
```

**Fig. 6.3** | Programmer-declared method `maximum` with three `double` parameters. (Part 2 of 2.)

### *The `public` and `static` Keywords*

Method `maximum`'s declaration begins with keyword `public` to indicate that the method is “available to the public”—it can be called from methods of other classes. The keyword `static` enables the `main` method (another `static` method) to call `maximum` as shown in line 21 without qualifying the method name with the class name `MaximumFinder`—`static` methods in the same class can call each other directly. Any other class that uses `maximum` must fully qualify the method name with the class name.

### *Method `maximum`*

Consider `maximum`'s declaration (lines 28–41). Line 28 indicates that it returns a `double` value, that the method's name is `maximum` and that the method requires three `double` pa-

parameters (*x*, *y* and *z*) to accomplish its task. Multiple parameters are specified as a comma-separated list. When `maximum` is called from line 21, the parameters *x*, *y* and *z* are initialized with the values of arguments `number1`, `number2` and `number3`, respectively. There must be one argument in the method call for each parameter in the method declaration. Also, each argument must be *consistent* with the type of the corresponding parameter. For example, a parameter of type `double` can receive values like 7.35, 22 or `-0.03456`, but not Strings like `"hello"` nor the boolean values `true` or `false`. Section 6.7 discusses the argument types that can be provided in a method call for each parameter of a primitive type.

To determine the maximum value, we begin with the assumption that parameter *x* contains the largest value, so line 30 declares local variable `maximumValue` and initializes it with the value of parameter *x*. Of course, it's possible that parameter *y* or *z* contains the actual largest value, so we must compare each of these values with `maximumValue`. The `if` statement at lines 33–34 determines whether *y* is greater than `maximumValue`. If so, line 34 assigns *y* to `maximumValue`. The `if` statement at lines 37–38 determines whether *z* is greater than `maximumValue`. If so, line 38 assigns *z* to `maximumValue`. At this point the largest of the three values resides in `maximumValue`, so line 40 returns that value to line 21. When program control returns to the point in the program where `maximum` was called, `maximum`'s parameters *x*, *y* and *z* no longer exist in memory.

### Software Engineering Observation 6.5

*Methods can return at most one value, but the returned value could be a reference to an object that contains many values.*

### Software Engineering Observation 6.6

*Variables should be declared as fields only if they're required for use in more than one method of the class or if the program should save their values between calls to the class's methods.*

### Common Programming Error 6.1

*Declaring method parameters of the same type as `float x, y` instead of `float x, float y` is a syntax error—a type is required for each parameter in the parameter list.*

## Implementing Method `maximum` by Reusing Method `Math.max`

The entire body of our `maximum` method could also be implemented with two calls to `Math.max`, as follows:

```
return Math.max( x, Math.max( y, z ) );
```

The first call to `Math.max` specifies arguments *x* and `Math.max( y, z )`. *Before* any method can be called, its arguments must be evaluated to determine their values. If an argument is a method call, the method call must be performed to determine its return value. So, in the preceding statement, `Math.max( y, z )` is evaluated to determine the maximum of *y* and *z*. Then the result is passed as the second argument to the other call to `Math.max`, which returns the larger of its two arguments. This is a good example of software reuse—we find the largest of three values by reusing `Math.max`, which finds the larger of two values. Note how concise this code is compared to lines 30–38 of Fig. 6.3.

## Assembling Strings with String Concatenation

Java allows you to assemble `String` objects into larger strings by using operators `+` or `+=`. This is known as **string concatenation**. When both operands of operator `+` are `String` ob-

jects, operator `+` creates a new `String` object in which the characters of the right operand are placed at the end of those in the left operand—e.g., the expression `"hello" + "there"` creates the `String` `"hello there"`.

In line 24 of Fig. 6.3, the expression `"Maximum is: " + result` uses operator `+` with operands of types `String` and `double`. *Every primitive value and object in Java has a String representation.* When one of the `+` operator's operands is a `String`, the other is converted to a `String`, then the two are *concatenated*. In line 24, the `double` value is converted to its `String` representation and placed at the end of the `String` `"Maximum is: "`. If there are any *trailing zeros* in a `double` value, these will be *discarded* when the number is converted to a `String`—for example 9.3500 would be represented as 9.35.

Primitive values used in `String` concatenation are converted to `Strings`. A `boolean` concatenated with a `String` is converted to the `String` `"true"` or `"false"`. All objects have a `toString` method that returns a `String` representation of the object. (We discuss `toString` in more detail in subsequent chapters.) When an object is concatenated with a `String`, the object's `toString` method is implicitly called to obtain the `String` representation of the object. `ToString` can be called explicitly.

You can break large `String` literals into several smaller `Strings` and place them on multiple lines of code for readability. In this case, the `Strings` can be reassembled using concatenation. We discuss the details of `Strings` in Chapter 16.

### Common Programming Error 6.2

*It's a syntax error to break a `String` literal across lines. If necessary, you can split a `String` into several smaller `Strings` and use concatenation to form the desired `String`.*

### Common Programming Error 6.3\

*Confusing the `+` operator used for string concatenation with the `+` operator used for addition can lead to strange results. Java evaluates the operands of an operator from left to right. For example, if integer variable `y` has the value 5, the expression `"y + 2 = " + y + 2` results in the string `"y + 2 = 52"`, not `"y + 2 = 7"`, because first the value of `y` (5) is concatenated to the string `"y + 2 = "`, then the value 2 is concatenated to the new larger string `"y + 2 = 5"`. The expression `"y + 2 = " + (y + 2)` produces the desired result `"y + 2 = 7"`.*

## 6.5 Notes on Declaring and Using Methods

There are three ways to call a method:

1. Using a method name by itself to call another method of the *same* class—such as `maximum(number1, number2, number3)` in line 21 of Fig. 6.3.
2. Using a variable that contains a reference to an object, followed by a dot (`.`) and the method name to call a non-static method of the referenced object—such as the method call in line 13 of Fig. 5.10, `myGradeBook.displayMessage()`, which calls a method of class `GradeBook` from the `main` method of `GradeBookTest`.
3. Using the class name and a dot (`.`) to call a static method of a class—such as `Math.sqrt(900.0)` in Section 6.3.

A static method can call *only* other static methods of the same class directly (i.e., using the method name by itself) and can manipulate *only* static variables in the same class directly. To access the class's non-static members, a static method must use a ref-

erence to an object of the class. Recall that `static` methods relate to a class as a whole, whereas non-`static` methods are associated with a specific instance (object) of the class and may manipulate the instance variables of that object. Many objects of a class, each with its own copies of the instance variables, may exist at the same time. Suppose a `static` method were to invoke a non-`static` method directly. How would the method know which object's instance variables to manipulate? What would happen if no objects of the class existed at the time the non-`static` method was invoked? Thus, Java does not allow a `static` method to access non-`static` members of the same class directly.

There are three ways to return control to the statement that calls a method. If the method does not return a result, control returns when the program flow reaches the method-ending right brace or when the statement

```
return;
```

is executed. If the method returns a result, the statement

```
return expression;
```

evaluates the *expression*, then returns the result to the caller.

#### Common Programming Error 6.4

*Declaring a method outside the body of a class declaration or inside the body of another method is a syntax error.*

#### Common Programming Error 6.5

*Placing a semicolon after the right parenthesis enclosing the parameter list of a method declaration is a syntax error.*

#### Common Programming Error 6.6

*Redeclaring a parameter as a local variable in the method's body is a compilation error.*

#### Common Programming Error 6.7

*Forgetting to return a value from a method that should return a value is a compilation error. If a return type other than `void` is specified, the method must contain a return statement that returns a value consistent with the method's return type. Returning a value from a method whose return type has been declared `void` is a compilation error.*

## 6.6 Method-Call Stack and Activation Records

To understand how Java performs method calls, we first need to consider a data structure (i.e., collection of related data items) known as a **stack**. You can think of a stack as analogous to a pile of dishes. When a dish is placed on the pile, it's normally placed at the top (referred to as **pushing** the dish onto the stack). Similarly, when a dish is removed from the pile, it's always removed from the top (referred to as **popping** the dish off the stack). Stacks are known as **last-in, first-out (LIFO) data structures**—the last item pushed (inserted) on the stack is the first item popped (removed) from the stack.

When a program calls a method, the called method must know how to return to its caller, so the return address of the calling method is pushed onto the **program-execution stack** (sometimes referred to as the **method-call stack**). If a series of method calls occurs, the successive return addresses are pushed onto the stack in last-in, first-out order so that each method can return to its caller.

The program-execution stack also contains the memory for the local variables used in each invocation of a method during a program's execution. This data, stored as a portion of the program-execution stack, is known as the **activation record** or **stack frame** of the method call. When a method call is made, the activation record for that method call is pushed onto the program-execution stack. When the method returns to its caller, the activation record for this method call is popped off the stack and those local variables are no longer known to the program. If a local variable holding a reference to an object is the only variable in the program with a reference to that object, then, when the activation record containing that local variable is popped off the stack, the object can no longer be accessed by the program and will eventually be deleted from memory by the JVM during “garbage collection.” We discuss garbage collection in Section 8.10.

Of course, a computer's memory is finite, so only a certain amount can be used to store activation records on the program-execution stack. If more method calls occur than can have their activation records stored, an error known as a **stack overflow** occurs.

## 6.7 Argument Promotion and Casting

Another important feature of method calls is **argument promotion**—converting an argument's value, if possible, to the type that the method expects to receive in its corresponding parameter. For example, a program can call `Math.sqrt` with an `int` argument even though a `double` argument is expected. The statement

```
System.out.println( Math.sqrt( 4 ) );
```

correctly evaluates `Math.sqrt(4)` and prints the value `2.0`. The method declaration's parameter list causes Java to convert the `int` value `4` to the `double` value `4.0` before passing the value to method `sqrt`. Such conversions may lead to compilation errors if Java's **promotion rules** are not satisfied. These rules specify which conversions are allowed—that is, which ones can be performed without losing data. In the `sqrt` example above, an `int` is converted to a `double` without changing its value. However, converting a `double` to an `int` truncates the fractional part of the `double` value—thus, part of the value is lost. Converting large integer types to small integer types (e.g., `long` to `int`, or `int` to `short`) may also result in changed values.

The promotion rules apply to expressions containing values of two or more primitive types and to primitive-type values passed as arguments to methods. Each value is promoted to the “highest” type in the expression. Actually, the expression uses a temporary copy of each value—the types of the original values remain unchanged. Figure 6.4 lists the primitive types and the types to which each can be promoted. The valid promotions for a given type are always to a type higher in the table. For example, an `int` can be promoted to the higher types `long`, `float` and `double`.

Converting values to types lower in the table of Fig. 6.4 will result in different values if the lower type cannot represent the value of the higher type (e.g., the `int` value `2000000` cannot be represented as a `short`, and any floating-point number with digits after its decimal point cannot be represented in an integer type such as `long`, `int` or `short`). There-

| Type    | Valid promotions                                               |
|---------|----------------------------------------------------------------|
| double  | None                                                           |
| float   | double                                                         |
| long    | float or double                                                |
| int     | long, float or double                                          |
| char    | int, long, float or double                                     |
| short   | int, long, float or double (but not char)                      |
| byte    | short, int, long, float or double (but not char)               |
| boolean | None (boolean values are not considered to be numbers in Java) |

**Fig. 6.4** | Promotions allowed for primitive types.

fore, in cases where information may be lost due to conversion, the Java compiler requires you to use a cast operator (introduced in Section 4.9) to explicitly force the conversion to occur—otherwise a compilation error occurs. This enables you to “take control” from the compiler. You essentially say, “I know this conversion might cause loss of information, but for my purposes here, that’s fine.” Suppose method `square` calculates the square of an integer and thus requires an `int` argument. To call `square` with a `double` argument named `doubleValue`, we would be required to write the method call as

```
square( (int) doubleValue )
```

This method call explicitly casts (converts) a *copy* of variable `doubleValue`’s value to an integer for use in method `square`. Thus, if `doubleValue`’s value is 4.5, the method receives the value 4 and returns 16, not 20.25.

### Common Programming Error 6.8

*Converting a primitive-type value to another primitive type may change the value if the new type is not a valid promotion. For example, converting a floating-point value to an integer value may introduce truncation errors (loss of the fractional part) into the result.*

## 6.8 Java API Packages

As you’ve seen, Java contains many predefined classes that are grouped into categories of related classes called packages. Together, these are known as the Java Application Programming Interface (Java API), or the Java class library. A great strength of Java is the Java API’s thousands of classes. Some key Java API packages are described in Fig. 6.5, which represents only a small portion of the reusable components in the Java API.

The set of packages available in Java SE 6 is quite large. In addition to those summarized in Fig. 6.5, Java SE 6 includes packages for complex graphics, advanced graphical user interfaces, printing, advanced networking, security, database processing, multimedia, accessibility (for people with disabilities), concurrent programming, cryptography, XML processing and many other capabilities. For an overview of the packages in Java SE 6, visit

```
download.oracle.com/javase/6/docs/api/overview-summary.html
```

Many other packages are also available for download at `java.sun.com`.

| Package                           | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>java.applet</code>          | The <b>Java Applet Package</b> contains a class and several interfaces required to create Java applets—programs that execute in web browsers. Applets are discussed in Chapter 23, Applets and Java Web Start; interfaces are discussed in Chapter 10, Object-Oriented Programming: Polymorphism.)                                                                                                                                                           |
| <code>java.awt</code>             | The <b>Java Abstract Window Toolkit Package</b> contains the classes and interfaces required to create and manipulate GUIs in early versions of Java. In current versions, the Swing GUI components of the <code>javax.swing</code> packages are typically used instead. (Some elements of the <code>java.awt</code> package are discussed in Chapter 14, GUI Components: Part 1, Chapter 15, Graphics and Java 2D, and Chapter 25, GUI Components: Part 2.) |
| <code>java.awt.event</code>       | The <b>Java Abstract Window Toolkit Event Package</b> contains classes and interfaces that enable event handling for GUI components in both the <code>java.awt</code> and <code>javax.swing</code> packages. (See Chapter 14, GUI Components: Part 1, and Chapter 25, GUI Components: Part 2.)                                                                                                                                                               |
| <code>java.awt.geom</code>        | The <b>Java 2D Shapes Package</b> contains classes and interfaces for working with Java's advanced two-dimensional graphics capabilities. (See Chapter 15, Graphics and Java 2D.)                                                                                                                                                                                                                                                                            |
| <code>java.io</code>              | The <b>Java Input/Output Package</b> contains classes and interfaces that enable programs to input and output data. (See Chapter 17, Files, Streams and Object Serialization.)                                                                                                                                                                                                                                                                               |
| <code>java.lang</code>            | The <b>Java Language Package</b> contains classes and interfaces (discussed bookwide) that are required by many Java programs. This package is imported by the compiler into all programs.                                                                                                                                                                                                                                                                   |
| <code>java.net</code>             | The <b>Java Networking Package</b> contains classes and interfaces that enable programs to communicate via computer networks like the Internet. (See Chapter 27, Networking.)                                                                                                                                                                                                                                                                                |
| <code>java.sql</code>             | The <b>JDBC Package</b> contains classes and interfaces for working with databases. (See Chapter 28, Accessing Databases with JDBC.)                                                                                                                                                                                                                                                                                                                         |
| <code>java.util</code>            | The <b>Java Utilities Package</b> contains utility classes and interfaces that enable such actions as date and time manipulations, random-number processing (class <code>Random</code> ) and the storing and processing of large amounts of data. (See Chapter 20, Generic Collections.)                                                                                                                                                                     |
| <code>java.util.concurrent</code> | The <b>Java Concurrency Package</b> contains utility classes and interfaces for implementing programs that can perform multiple tasks in parallel. (See Chapter 26, Multithreading.)                                                                                                                                                                                                                                                                         |
| <code>javax.media</code>          | The <b>Java Media Framework Package</b> contains classes and interfaces for working with Java's multimedia capabilities. (See Chapter 24, Multimedia: Applets and Applications.)                                                                                                                                                                                                                                                                             |
| <code>javax.swing</code>          | The <b>Java Swing GUI Components Package</b> contains classes and interfaces for Java's Swing GUI components that provide support for portable GUIs. (See Chapter 14, GUI Components: Part 1, and Chapter 25, GUI Components: Part 2.)                                                                                                                                                                                                                       |

**Fig. 6.5** | Java API packages (a subset). (Part 1 of 2.)

| Package                        | Description                                                                                                                                                                                                                                                                   |
|--------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>javax.swing.event</code> | The <b>Java Swing Event Package</b> contains classes and interfaces that enable event handling (e.g., responding to button clicks) for GUI components in package <code>javax.swing</code> . (See Chapter 14, GUI Components: Part 1, and Chapter 25, GUI Components: Part 2.) |
| <code>javax.xml.ws</code>      | The <b>JAX-WS Package</b> contains classes and interfaces for working with web services in Java. (See Chapter 31, Web Services.)                                                                                                                                              |

**Fig. 6.5** | Java API packages (a subset). (Part 2 of 2.)

You can locate additional information about a predefined Java class’s methods in the Java API documentation at [download.oracle.com/javase/6/docs/api/](http://download.oracle.com/javase/6/docs/api/). When you visit this site, click the **Index** link to see an alphabetical listing of all the classes and methods in the Java API. Locate the class name and click its link to see the online description of the class. Click the **METHOD** link to see a table of the class’s methods. Each `static` method will be listed with the word “`static`” preceding its return type.

## 6.9 Case Study: Random-Number Generation

We now take a brief diversion into a popular type of programming application—simulation and game playing. In this and the next section, we develop a nicely structured game-playing program with multiple methods. The program uses most of the control statements presented thus far in the book and introduces several new programming concepts.

There’s something in the air of a casino that invigorates people—from the high rollers at the plush mahogany-and-felt craps tables to the quarter poppers at the one-armed bandits. It’s the **element of chance**, the possibility that luck will convert a pocketful of money into a mountain of wealth. The element of chance can be introduced in a program via an object of class **Random** (package `java.util`) or via the `static` method `random` of class `Math`. Objects of class `Random` can produce random `boolean`, `byte`, `float`, `double`, `int`, `long` and Gaussian values, whereas `Math` method `random` can produce only `double` values in the range  $0.0 \leq x < 1.0$ , where  $x$  is the value returned by method `random`. In the next several examples, we use objects of class `Random` to produce random values.

A new random-number generator object can be created as follows:

```
Random randomNumbers = new Random();
```

It can then be used to generate random `boolean`, `byte`, `float`, `double`, `int`, `long` and Gaussian values—we discuss only random `int` values here. For more information on the `Random` class, see [download.oracle.com/javase/6/docs/api/java/util/Random.html](http://download.oracle.com/javase/6/docs/api/java/util/Random.html).

Consider the following statement:

```
int randomValue = randomNumbers.nextInt();
```

`Random` method **`nextInt`** generates a random `int` value in the range  $-2,147,483,648$  to  $+2,147,483,647$ , inclusive. If it truly produces values at random, then every value in the range should have an equal chance (or probability) of being chosen each time `nextInt` is called. The numbers are actually **pseudorandom numbers**—a sequence of values pro-

duced by a complex mathematical calculation. The calculation uses the current time of day (which, of course, changes constantly) to **seed** the random-number generator such that each execution of a program yields a different sequence of random values.

The range of values produced directly by method `nextInt` generally differs from the range of values required in a particular Java application. For example, a program that simulates coin tossing might require only 0 for “heads” and 1 for “tails.” A program that simulates the rolling of a six-sided die might require random integers in the range 1–6. A program that randomly predicts the next type of spaceship (out of four possibilities) that will fly across the horizon in a video game might require random integers in the range 1–4. For cases like these, class `Random` provides another version of method `nextInt` that receives an `int` argument and returns a value from 0 up to, but not including, the argument’s value. For example, for coin tossing, the following statement returns 0 or 1.

```
int randomValue = randomNumbers.nextInt( 2 );
```

### *Rolling a Six-Sided Die*

To demonstrate random numbers, let’s develop a program that simulates 20 rolls of a six-sided die and displays the value of each roll. We begin by using `nextInt` to produce random values in the range 0–5, as follows:

```
face = randomNumbers.nextInt( 6 );
```

The argument 6—called the **scaling factor**—represents the number of unique values that `nextInt` should produce (in this case six—0, 1, 2, 3, 4 and 5). This manipulation is called **scaling** the range of values produced by `Random` method `nextInt`.

A six-sided die has the numbers 1–6 on its faces, not 0–5. So we **shift** the range of numbers produced by adding a **shifting value**—in this case 1—to our previous result, as in

```
face = 1 + randomNumbers.nextInt( 6 );
```

The shifting value (1) specifies the *first* value in the desired range of random integers. The preceding statement assigns `face` a random integer in the range 1–6.

Figure 6.6 shows two sample outputs which confirm that the results of the preceding calculation are integers in the range 1–6, and that each run of the program can produce a different sequence of random numbers. Line 3 imports class `Random` from the `java.util` package. Line 9 creates the `Random` object `randomNumbers` to produce random values. Line 16 executes 20 times in a loop to roll the die. The `if` statement (lines 21–22) in the loop starts a new line of output after every five numbers.

---

```
1 // Fig. 6.6: RandomIntegers.java
2 // Shifted and scaled random integers.
3 import java.util.Random; // program uses class Random
4
5 public class RandomIntegers
6 {
7     public static void main( String[] args )
8     {
9         Random randomNumbers = new Random(); // random number generator
```

---

**Fig. 6.6** | Shifted and scaled random integers. (Part 1 of 2.)

```

10     int face; // stores each random integer generated
11
12     // loop 20 times
13     for ( int counter = 1; counter <= 20; counter++ )
14     {
15         // pick random integer from 1 to 6
16         face = 1 + randomNumbers.nextInt( 6 );
17
18         System.out.printf( "%d ", face ); // display generated value
19
20         // if counter is divisible by 5, start a new line of output
21         if ( counter % 5 == 0 )
22             System.out.println();
23     } // end for
24 } // end main
25 } // end class RandomIntegers

```

```

1 5 3 6 2
5 2 6 5 2
4 4 4 2 6
3 1 6 2 2

```

```

6 5 4 2 6
1 2 5 1 3
6 3 2 2 1
6 4 2 6 4

```

**Fig. 6.6** | Shifted and scaled random integers. (Part 2 of 2.)

### *Rolling a Six-Sided Die 6,000,000 Times*

To show that the numbers produced by `nextInt` occur with approximately equal likelihood, let's simulate 6,000,000 rolls of a die with the application in Fig. 6.7. Each integer from 1 to 6 should appear approximately 1,000,000 times.

```

1 // Fig. 6.7: RollDie.java
2 // Roll a six-sided die 6,000,000 times.
3 import java.util.Random;
4
5 public class RollDie
6 {
7     public static void main( String[] args )
8     {
9         Random randomNumbers = new Random(); // random number generator
10
11         int frequency1 = 0; // maintains count of 1s rolled
12         int frequency2 = 0; // count of 2s rolled
13         int frequency3 = 0; // count of 3s rolled
14         int frequency4 = 0; // count of 4s rolled
15         int frequency5 = 0; // count of 5s rolled
16         int frequency6 = 0; // count of 6s rolled
17

```

**Fig. 6.7** | Roll a six-sided die 6,000,000 times. (Part 1 of 2.)

```

18     int face; // most recently rolled value
19
20     // tally counts for 6,000,000 rolls of a die

**Fig. 6.7** | Roll a six-sided die 6,000,000 times. (Part 2 of 2.)

As the sample outputs show, scaling and shifting the values produced by `nextInt` enables the program to simulate rolling a six-sided die. The application uses nested control statements (the `switch` is nested inside the `for`) to determine the number of times each side of the die appears. The `for` statement (lines 21–47) iterates 6,000,000 times. During each iteration, line 23 produces a random value from 1 to 6. That value is then used as the controlling expression (line 26) of the `switch` statement (lines 26–46). Based on the face value, the `switch` statement increments one of the six counter variables during each iteration of the loop. When we study arrays in Chapter 7, we'll show an elegant way to replace the entire `switch` statement in this program with a single statement! This `switch` statement has no `default` case, because we have a case for every possible die value that the expression in line 23 could produce. Run the program, and observe the results. As you'll see, every time you run this program, it produces different results.

### 6.9.1 Generalized Scaling and Shifting of Random Numbers

Previously, we simulated the rolling of a six-sided die with the statement

```
face = 1 + randomNumbers.nextInt( 6 );
```

This statement always assigns to variable `face` an integer in the range  $1 \leq \text{face} \leq 6$ . The width of this range (i.e., the number of consecutive integers in the range) is 6, and the starting number in the range is 1. In the preceding statement, the width of the range is determined by the number 6 that's passed as an argument to `Random` method `nextInt`, and the starting number of the range is the number 1 that's added to `randomNumberGenerator.nextInt(6)`. We can generalize this result as

```
number = shiftingValue + randomNumbers.nextInt( scalingFactor );
```

where *shiftingValue* specifies the first number in the desired range of consecutive integers and *scalingFactor* specifies how many numbers are in the range.

It's also possible to choose integers at random from sets of values other than ranges of consecutive integers. For example, to obtain a random value from the sequence 2, 5, 8, 11 and 14, you could use the statement

```
number = 2 + 3 * randomNumbers.nextInt( 5 );
```

In this case, `randomNumberGenerator.nextInt(5)` produces values in the range 0–4. Each value produced is multiplied by 3 to produce a number in the sequence 0, 3, 6, 9 and 12. We add 2 to that value to shift the range of values and obtain a value from the sequence 2, 5, 8, 11 and 14. We can generalize this result as

```
number = shiftingValue +  
         differenceBetweenValues * randomNumbers.nextInt( scalingFactor );
```

where *shiftingValue* specifies the first number in the desired range of values, *differenceBetweenValues* represents the constant difference between consecutive numbers in the sequence and *scalingFactor* specifies how many numbers are in the range.

### 6.9.2 Random-Number Repeatability for Testing and Debugging

Class `Random`'s methods actually generate pseudorandom numbers based on complex mathematical calculations—the sequence of numbers appears to be random. The calculation that produces the numbers uses the time of day as a **seed value** to change the se-

quence's starting point. Each new `Random` object seeds itself with a value based on the computer system's clock at the time the object is created, enabling each execution of a program to produce a different sequence of random numbers.

When debugging an application, it's often useful to repeat the exact same sequence of pseudorandom numbers during each execution of the program. This repeatability enables you to prove that your application is working for a specific sequence of random numbers before you test it with different sequences of random numbers. When repeatability is important, you can create a `Random` object as follows:

```
Random randomNumbers = new Random( seedValue );
```

The `seedValue` argument (of type `long`) seeds the random-number calculation. If the same `seedValue` is used every time, the `Random` object produces the same sequence of numbers. You can set a `Random` object's seed at any time during program execution by calling the object's `set` method, as in

```
randomNumbers.set( seedValue );
```

### Error-Prevention Tip 6.2

While developing a program, create the `Random` object with a specific seed value to produce a repeatable sequence of numbers each time the program executes. If a logic error occurs, fix the error and test the program again with the same seed value—this allows you to reconstruct the same sequence of numbers that caused the error. Once the logic errors have been removed, create the `Random` object without using a seed value, causing the `Random` object to generate a new sequence of random numbers each time the program executes.

## 6.10 Case Study: A Game of Chance; Introducing Enumerations

A popular game of chance is a dice game known as craps, which is played in casinos and back alleys throughout the world. The rules of the game are straightforward:

*You roll two dice. Each die has six faces, which contain one, two, three, four, five and six spots, respectively. After the dice have come to rest, the sum of the spots on the two upward faces is calculated. If the sum is 7 or 11 on the first throw, you win. If the sum is 2, 3 or 12 on the first throw (called “craps”), you lose (i.e., the “house” wins). If the sum is 4, 5, 6, 8, 9 or 10 on the first throw, that sum becomes your “point.” To win, you must continue rolling the dice until you “make your point” (i.e., roll that same point value). You lose by rolling a 7 before making your point.*

Figure 6.8 simulates the game of craps, using methods to implement the game's logic. The main method (lines 21–65) calls the `rollDice` method (lines 68–81) as necessary to roll the dice and compute their sum. The sample outputs show winning and losing on the first roll, and winning and losing on a subsequent roll.

```
1 // Fig. 6.8: Craps.java
2 // Craps class simulates the dice game craps.
3 import java.util.Random;
```

**Fig. 6.8** | Craps class simulates the dice game craps. (Part 1 of 3.)

```
4
5 public class Craps
6 {
7     // create random number generator for use in method rollDice
8     private static final Random randomNumbers = new Random();
9
10    // enumeration with constants that represent the game status
11    private enum Status { CONTINUE, WON, LOST };
12
13    // constants that represent common rolls of the dice
14    private static final int SNAKE_EYES = 2;
15    private static final int TREY = 3;
16    private static final int SEVEN = 7;
17    private static final int YO_LEVEN = 11;
18    private static final int BOX_CARS = 12;
19
20    // plays one game of craps
21    public static void main( String[] args )
22    {
23        int myPoint = 0; // point if no win or loss on first roll
24        Status gameStatus; // can contain CONTINUE, WON or LOST
25
26        int sumOfDice = rollDice(); // first roll of the dice
27
28        // determine game status and point based on first roll
29        switch ( sumOfDice )
30        {
31            case SEVEN: // win with 7 on first roll
32            case YO_LEVEN: // win with 11 on first roll
33                gameStatus = Status.WON;
34                break;
35            case SNAKE_EYES: // lose with 2 on first roll
36            case TREY: // lose with 3 on first roll
37            case BOX_CARS: // lose with 12 on first roll
38                gameStatus = Status.LOST;
39                break;
40            default: // did not win or lose, so remember point
41                gameStatus = Status.CONTINUE; // game is not over
42                myPoint = sumOfDice; // remember the point
43                System.out.printf( "Point is %d\n", myPoint );
44                break; // optional at end of switch
45        } // end switch
46
47        // while game is not complete
48        while ( gameStatus == Status.CONTINUE ) // not WON or LOST
49        {
50            sumOfDice = rollDice(); // roll dice again
51
52            // determine game status
53            if ( sumOfDice == myPoint ) // win by making point
54                gameStatus = Status.WON;
```

**Fig. 6.8** | Craps class simulates the dice game craps. (Part 2 of 3.)

```

55         else
56             if ( sumOfDice == SEVEN ) // lose by rolling 7 before point
57                 gameStatus = Status.LOST;
58         } // end while
59
60         // display won or lost message
61         if ( gameStatus == Status.WON )
62             System.out.println( "Player wins" );
63         else
64             System.out.println( "Player loses" );
65     } // end main
66
67     // roll dice, calculate sum and display results
68     public static int rollDice()
69     {
70         // pick random die values
71         int die1 = 1 + randomNumbers.nextInt( 6 ); // first die roll
72         int die2 = 1 + randomNumbers.nextInt( 6 ); // second die roll
73
74         int sum = die1 + die2; // sum of die values
75
76         // display results of this roll
77         System.out.printf( "Player rolled %d + %d = %d\n",
78             die1, die2, sum );
79
80         return sum; // return sum of dice
81     } // end method rollDice
82 } // end class Craps

```

```

Player rolled 5 + 6 = 11
Player wins

```

```

Player rolled 5 + 4 = 9
Point is 9
Player rolled 4 + 2 = 6
Player rolled 3 + 6 = 9
Player wins

```

```

Point is 8
Player rolled 5 + 1 = 6
Player rolled 2 + 1 = 3
Player rolled 1 + 6 = 7
Player loses

```

**Fig. 6.8** | Craps class simulates the dice game craps. (Part 3 of 3.)

### Method `rollDice`

In the rules of the game, the player must roll two dice on the first roll and must do the same on all subsequent rolls. We declare method `rollDice` (Fig. 6.8, lines 68–81) to roll the dice and compute and print their sum. Method `rollDice` is declared once, but it’s called from two places (lines 26 and 50) in `main`, which contains the logic for one complete game of craps. Method `rollDice` takes no arguments, so it has an empty parameter list. Each time it’s called, `rollDice` returns the sum of the dice, so the return type `int` is indicated in the method header (line 68). Although lines 71 and 72 look the same (except for the die names), they do not necessarily produce the same result. Each of these statements produces a random value in the range 1–6. Variable `randomNumbers` (used in lines 71–72) is *not* declared in the method. Instead it’s declared as a `private static final` variable of the class and initialized in line 8. This enables us to create one `Random` object that’s reused in each call to `rollDice`. If there were a program that contained multiple instances of class `Craps`, they’d all share this one `Random` object.

### Method `main`’s Local Variables

The game is reasonably involved. The player may win or lose on the first roll, or may win or lose on any subsequent roll. Method `main` (lines 21–65) uses local variable `myPoint` (line 23) to store the “point” if the player does not win or lose on the first roll, local variable `gameStatus` (line 24) to keep track of the overall game status and local variable `sumOfDice` (line 26) to hold the sum of the dice for the most recent roll. Variable `myPoint` is initialized to 0 to ensure that the application will compile. If you do not initialize `myPoint`, the compiler issues an error, because `myPoint` is not assigned a value in *every* case of the `switch` statement, and thus the program could try to use `myPoint` before it’s assigned a value. By contrast, `gameStatus` *is* assigned a value in *every* case of the `switch` statement—thus, it’s guaranteed to be initialized before it’s used and does not need to be initialized.

### enum Type Status

Local variable `gameStatus` (line 24) is declared to be of a new type called `Status` (declared at line 11). Type `Status` is a private member of class `Craps`, because `Status` will be used only in that class. `Status` is a type called an **enumeration**, which, in its simplest form, declares a set of constants represented by identifiers. An enumeration is a special kind of class that’s introduced by the keyword **enum** and a type name (in this case, `Status`). As with classes, braces delimit an enum declaration’s body. Inside the braces is a comma-separated list of **enumeration constants**, each representing a unique value. The identifiers in an enum must be unique. You’ll learn more about enumerations in Chapter 8.

#### Good Programming Practice 6.1

*It’s a convention to use only uppercase letters in the names of enumeration constants. This makes them stand out and reminds you that they are not variables.*

Variables of type `Status` can be assigned only the three constants declared in the enumeration (line 11) or a compilation error will occur. When the game is won, the program sets local variable `gameStatus` to `Status.WON` (lines 33 and 54). When the game is lost, the program sets local variable `gameStatus` to `Status.LOST` (lines 38 and 57). Otherwise, the program sets local variable `gameStatus` to `Status.CONTINUE` (line 41) to indicate that the game is not over and the dice must be rolled again.

### Good Programming Practice 6.2

Using enumeration constants (like `Status.WON`, `Status.LOST` and `Status.CONTINUE`) rather than literal values (such as 0, 1 and 2) makes programs easier to read and maintain.

#### Logic of the `main` Method

Line 26 in `main` calls `rollDice`, which picks two random values from 1 to 6, displays the values of the first die, the second die and their sum, and returns the sum. Method `main` next enters the `switch` statement (lines 29–45), which uses the `sumOfDice` value from line 26 to determine whether the game has been won or lost, or should continue with another roll. The values that result in a win or loss on the first roll are declared as `public static final int` constants in lines 14–18. The identifier names use casino parlance for these sums. These constants, like `enum` constants, are declared by convention with all capital letters, to make them stand out in the program. Lines 31–34 determine whether the player won on the first roll with `SEVEN` (7) or `YO_LEVEN` (11). Lines 35–39 determine whether the player lost on the first roll with `SNAKE_EYES` (2), `TREY` (3), or `BOX_CARS` (12). After the first roll, if the game is not over, the default case (lines 40–44) sets `gameStatus` to `Status.CONTINUE`, saves `sumOfDice` in `myPoint` and displays the point.

If we're still trying to "make our point" (i.e., the game is continuing from a prior roll), lines 48–58 execute. Line 50 rolls the dice again. If `sumOfDice` matches `myPoint` (line 53), line 54 sets `gameStatus` to `Status.WON`, then the loop terminates because the game is complete. If `sumOfDice` is `SEVEN` (line 56), line 57 sets `gameStatus` to `Status.LOST`, and the loop terminates because the game is complete. When the game completes, lines 61–64 display a message indicating whether the player won or lost, and the program terminates.

The program uses the various program-control mechanisms we've discussed. The `Craps` class uses two methods—`main` and `rollDice` (called twice from `main`)—and the `switch`, `while`, `if...else` and nested `if` control statements. Note also the use of multiple case labels in the `switch` statement to execute the same statements for sums of `SEVEN` and `YO_LEVEN` (lines 31–32) and for sums of `SNAKE_EYES`, `TREY` and `BOX_CARS` (lines 35–37).

#### Why Some Constants Are Not Defined as `enum` Constants

You might be wondering why we declared the sums of the dice as `public final static int` constants rather than as `enum` constants. The reason is that the program must compare the `int` variable `sumOfDice` (line 26) to these constants to determine the outcome of each roll. Suppose we declared `enum Sum` containing constants (e.g., `Sum.SNAKE_EYES`) representing the five sums used in the game, then used these constants in the `switch` statement (lines 29–45). Doing so would prevent us from using `sumOfDice` as the `switch` statement's controlling expression, because Java does *not* allow an `int` to be compared to an enumeration constant. To achieve the same functionality as the current program, we would have to use a variable `currentSum` of type `Sum` as the `switch`'s controlling expression. Unfortunately, Java does not provide an easy way to convert an `int` value to a particular `enum` constant. This could be done with a separate `switch` statement. Clearly this would be cumbersome and not improve the program's readability (thus defeating the purpose of using an `enum`).

## 6.11 Scope of Declarations

You've seen declarations of various Java entities, such as classes, methods, variables and parameters. Declarations introduce names that can be used to refer to such Java entities. The

**scope** of a declaration is the portion of the program that can refer to the declared entity by its name. Such an entity is said to be “in scope” for that portion of the program. This section introduces several important scope issues.

The basic scope rules are as follows:

1. The scope of a parameter declaration is the body of the method in which the declaration appears.
2. The scope of a local-variable declaration is from the point at which the declaration appears to the end of that block.
3. The scope of a local-variable declaration that appears in the initialization section of a `for` statement’s header is the body of the `for` statement and the other expressions in the header.
4. A method or field’s scope is the entire body of the class. This enables non-static methods of a class to use the fields and other methods of the class.

Any block may contain variable declarations. If a local variable or parameter in a method has the same name as a field of the class, the field is “hidden” until the block terminates execution—this is called **shadowing**. In Chapter 8, we discuss how to access shadowed fields.

### Error-Prevention Tip 6.3

*Use different names for fields and local variables to help prevent subtle logic errors that occur when a method is called and a local variable of the method shadows a field in the class.*

Figure 6.9 demonstrates scoping issues with fields and local variables. Line 7 declares and initializes the field `x` to 1. This field is shadowed (hidden) in any block (or method) that declares a local variable named `x`. Method `main` (lines 11–23) declares a local variable `x` (line 13) and initializes it to 5. This local variable’s value is output to show that the field `x` (whose value is 1) is shadowed in `main`. The program declares two other methods—`useLocalVariable` (lines 26–35) and `useField` (lines 38–45)—that each take no arguments and return no results. Method `main` calls each method twice (lines 17–20). Method `useLocalVariable` declares local variable `x` (line 28). When `useLocalVariable` is first called (line 17), it creates local variable `x` and initializes it to 25 (line 28), outputs the value of `x` (lines 30–31), increments `x` (line 32) and outputs the value of `x` again (lines 33–34). When `useLocalVariable` is called a second time (line 19), it recreates local variable `x` and re-initializes it to 25, so the output of each `useLocalVariable` call is identical.

```

1 // Fig. 6.9: Scope.java
2 // Scope class demonstrates field and local variable scopes.
3
4 public class Scope
5 {
6     // field that is accessible to all methods of this class
7     private static int x = 1;
8

```

**Fig. 6.9** | Scope class demonstrates field and local variable scopes. (Part 1 of 2.)

```

 9 // method main creates and initializes local variable x
10 // and calls methods useLocalVariable and useField
11 public static void main( String[] args )
12 {
13     int x = 5; // method's local variable x shadows field x
14
15     System.out.printf( "local x in main is %d\n", x );
16
17     useLocalVariable(); // useLocalVariable has local x
18     useField(); // useField uses class Scope's field x
19     useLocalVariable(); // useLocalVariable reinitializes local x
20     useField(); // class Scope's field x retains its value
21
22     System.out.printf( "\nlocal x in main is %d\n", x );
23 } // end main
24
25 // create and initialize local variable x during each call
26 public static void useLocalVariable()
27 {
28     int x = 25; // initialized each time useLocalVariable is called
29
30     System.out.printf(
31         "\nlocal x on entering method useLocalVariable is %d\n", x );
32     ++x; // modifies this method's local variable x
33     System.out.printf(
34         "local x before exiting method useLocalVariable is %d\n", x );
35 } // end method useLocalVariable
36
37 // modify class Scope's field x during each call
38 public static void useField()
39 {
40     System.out.printf(
41         "\nfield x on entering method useField is %d\n", x );
42     x *= 10; // modifies class Scope's field x
43     System.out.printf(
44         "field x before exiting method useField is %d\n", x );
45 } // end method useField
46 } // end class Scope

```

```

local x in main is 5

local x on entering method useLocalVariable is 25
local x before exiting method useLocalVariable is 26

field x on entering method useField is 1
field x before exiting method useField is 10

local x on entering method useLocalVariable is 25
local x before exiting method useLocalVariable is 26

field x on entering method useField is 10
field x before exiting method useField is 100

local x in main is 5

```

**Fig. 6.9** | Scope class demonstrates field and local variable scopes. (Part 2 of 2.)

Method `useField` does not declare any local variables. Therefore, when it refers to `x`, field `x` (line 7) of the class is used. When method `useField` is first called (line 18), it outputs the value (1) of field `x` (lines 40–41), multiplies the field `x` by 10 (line 42) and outputs the value (10) of field `x` again (lines 43–44) before returning. The next time method `useField` is called (line 20), the field has its modified value (10), so the method outputs 10, then 100. Finally, in method `main`, the program outputs the value of local variable `x` again (line 22) to show that none of the method calls modified `main`'s local variable `x`, because the methods all referred to variables named `x` in other scopes.

## 6.12 Method Overloading

Methods of the same name can be declared in the same class, as long as they have different sets of parameters (determined by the number, types and order of the parameters)—this is called **method overloading**. When an overloaded method is called, the compiler selects the appropriate method by examining the number, types and order of the arguments in the call. Method overloading is commonly used to create several methods with the *same* name that perform the *same* or *similar* tasks, but on different types or different numbers of arguments. For example, `Math` methods `abs`, `min` and `max` (summarized in Section 6.3) are overloaded with four versions each:

1. One with two `double` parameters.
2. One with two `float` parameters.
3. One with two `int` parameters.
4. One with two `long` parameters.

Our next example demonstrates declaring and invoking overloaded methods. We demonstrate overloaded constructors in Chapter 8.

### Declaring Overloaded Methods

Class `MethodOverload` (Fig. 6.10) includes two overloaded versions of method `square`—one that calculates the square of an `int` (and returns an `int`) and one that calculates the square of a `double` (and returns a `double`). Although these methods have the same name and similar parameter lists and bodies, think of them simply as *different* methods. It may help to think of the method names as “square of `int`” and “square of `double`,” respectively.

---

```

1 // Fig. 6.10: MethodOverload.java
2 // Overloaded method declarations.
3
4 public class MethodOverload
5 {
6     // test overloaded square methods
7     public static void main( String[] args )
8     {
9         System.out.printf( "Square of integer 7 is %d\n", square( 7 ) );
10        System.out.printf( "Square of double 7.5 is %f\n", square( 7.5 ) );
11    } // end main
12
```

---

**Fig. 6.10** | Overloaded method declarations. (Part 1 of 2.)

```

13 // square method with int argument
14 public static int square( int intValue )
15 {
16     System.out.printf( "\nCalled square with int argument: %d\n",
17         intValue );
18     return intValue * intValue;
19 } // end method square with int argument
20
21 // square method with double argument
22 public static double square( double doubleValue )
23 {
24     System.out.printf( "\nCalled square with double argument: %f\n",
25         doubleValue );
26     return doubleValue * doubleValue;
27 } // end method square with double argument
28 } // end class MethodOverload

```

```

Called square with int argument: 7
Square of integer 7 is 49

Called square with double argument: 7.500000
Square of double 7.5 is 56.250000

```

**Fig. 6.10** | Overloaded method declarations. (Part 2 of 2.)

Line 9 invokes method `square` with the argument 7. Literal integer values are treated as type `int`, so the method call in line 9 invokes the version of `square` at lines 14–19 that specifies an `int` parameter. Similarly, line 10 invokes method `square` with the argument 7.5. Literal floating-point values are treated as type `double`, so the method call in line 10 invokes the version of `square` at lines 22–27 that specifies a `double` parameter. Each method first outputs a line of text to prove that the proper method was called in each case. The values in lines 10 and 24 are displayed with the format specifier `%f`. We did not specify a precision in either case. By default, floating-point values are displayed with six digits of precision if the precision is not specified in the format specifier.

### *Distinguishing Between Overloaded Methods*

The compiler distinguishes overloaded methods by their **signature**—a combination of the method’s name and the number, types and order of its parameters. If the compiler looked only at method names during compilation, the code in Fig. 6.10 would be ambiguous—the compiler would not know how to distinguish between the two `square` methods (lines 14–19 and 22–27). Internally, the compiler uses longer method names that include the original method name, the types of each parameter and the exact order of the parameters to determine whether the methods in a class are unique in that class.

For example, in Fig. 6.10, the compiler might use the logical name “square of `int`” for the `square` method that specifies an `int` parameter and “square of `double`” for the `square` method that specifies a `double` parameter (the actual names the compiler uses are messier). If `method1`’s declaration begins as

```
void method1( int a, float b )
```

then the compiler might use the logical name “method1 of `int` and `float`.” If the parameters are specified as

```
void method1( float a, int b )
```

then the compiler might use the logical name “method1 of float and int.” The *order* of the parameter types is important—the compiler considers the preceding two method1 headers to be distinct.

### Return Types of Overloaded Methods

In discussing the logical names of methods used by the compiler, we did not mention the return types of the methods. *Method calls cannot be distinguished by return type.* If you had overloaded methods that differed only by their return types and you called one of the methods in a standalone statement as in:

```
square( 2 );
```

the compiler would *not* be able to determine the version of the method to call, because the return value is ignored. When two methods have the same signature and different return types, the compiler issues an error message indicating that the method is already defined in the class. Overloaded methods *can* have different return types if the methods have different parameter lists. Also, overloaded methods need *not* have the same number of parameters.

### Common Programming Error 6.9

*Declaring overloaded methods with identical parameter lists is a compilation error regardless of whether the return types are different.*

## 6.13 (Optional) GUI and Graphics Case Study: Colors and Filled Shapes

Although you can create many interesting designs with just lines and basic shapes, class `Graphics` provides many more capabilities. The next two features we introduce are colors and filled shapes. Adding color enriches the drawings a user sees on the computer screen. Shapes can be filled with solid colors.

Colors displayed on computer screens are defined by their red, green, and blue components (called **RGB values**) that have integer values from 0 to 255. The higher the value of a component color, the richer that shade will be in the final color. Java uses class `Color` in package `java.awt` to represent colors using their RGB values. For convenience, class `Color` (package `java.awt`) contains 13 predefined static `Color` objects—`BLACK`, `BLUE`, `CYAN`, `DARK_GRAY`, `GRAY`, `GREEN`, `LIGHT_GRAY`, `MAGENTA`, `ORANGE`, `PINK`, `RED`, `WHITE` and `YELLOW`. Each can be accessed via the class name and a dot (`.`) as in `Color.RED`. Class `Color` also contains a constructor of the form:

```
public Color( int r, int g, int b )
```

so you can create custom colors by specifying the values of the red, green and blue components.

Graphics methods `fillRect` and `fillOval` draw filled rectangles and ovals, respectively. These have the same parameters as `drawRect` and `drawOval`; the first two are the coordinates for the upper-left corner of the shape, while the next two determine the width and height. The example in Fig. 6.11 and Fig. 6.12 demonstrates colors and filled shapes by drawing and displaying a yellow smiley face on the screen.

```
1 // Fig. 6.11: DrawSmiley.java
2 // Demonstrates filled shapes.
3 import java.awt.Color;
4 import java.awt.Graphics;
5 import javax.swing.JPanel;
6
7 public class DrawSmiley extends JPanel
8 {
9     public void paintComponent( Graphics g )
10    {
11        super.paintComponent( g );
12
13        // draw the face
14        g.setColor( Color.YELLOW );
15        g.fillOval( 10, 10, 200, 200 );
16
17        // draw the eyes
18        g.setColor( Color.BLACK );
19        g.fillOval( 55, 65, 30, 30 );
20        g.fillOval( 135, 65, 30, 30 );
21
22        // draw the mouth
23        g.fillOval( 50, 110, 120, 60 );
24
25        // "touch up" the mouth into a smile
26        g.setColor( Color.YELLOW );
27        g.fillRect( 50, 110, 120, 30 );
28        g.fillOval( 50, 120, 120, 40 );
29    } // end method paintComponent
30 } // end class DrawSmiley
```

**Fig. 6.11** | Drawing a smiley face using colors and filled shapes.

The `import` statements in lines 3–5 of Fig. 6.11 import classes `Color`, `Graphics` and `JPanel`. Class `DrawSmiley` (lines 7–30) uses class `Color` to specify drawing colors, and uses class `Graphics` to draw.

Class `JPanel` again provides the area in which we draw. Line 14 in method `paintComponent` uses `Graphics` method `setColor` to set the current drawing color to `Color.YELLOW`. Method `setColor` requires one argument, the `Color` to set as the drawing color. In this case, we use the predefined object `Color.YELLOW`.

Line 15 draws a circle with diameter 200 to represent the face—when the width and height arguments are identical, method `fillOval` draws a circle. Next, line 18 sets the color to `Color.Black`, and lines 19–20 draw the eyes. Line 23 draws the mouth as an oval, but this is not quite what we want.

To create a happy face, we’ll “touch up” the mouth. Line 26 sets the color to `Color.YELLOW`, so any shapes we draw will blend in with the face. Line 27 draws a rectangle that’s half the mouth’s height. This “erases” the top half of the mouth, leaving just the bottom half. To create a better smile, line 28 draws another oval to slightly cover the upper portion of the mouth. Class `DrawSmileyTest` (Fig. 6.12) creates and displays a `JFrame` containing the drawing. When the `JFrame` is displayed, the system calls method `paintComponent` to draw the smiley face.

```
1 // Fig. 6.12: DrawSmileyTest.java
2 // Test application that displays a smiley face.
3 import javax.swing.JFrame;
4
5 public class DrawSmileyTest
6 {
7     public static void main( String[] args )
8     {
9         DrawSmiley panel = new DrawSmiley();
10        JFrame application = new JFrame();
11
12        application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
13        application.add( panel );
14        application.setSize( 230, 250 );
15        application.setVisible( true );
16    } // end main
17 } // end class DrawSmileyTest
```

**Fig. 6.12** | Creating JFrame to display a smiley face.

### *GUI and Graphics Case Study Exercises*

**6.1** Using method `fillOval`, draw a bull's-eye that alternates between two random colors, as in Fig. 6.13. Use the constructor `Color( int r, int g, int b )` with random arguments to generate random colors.

**Fig. 6.13** | A bull's-eye with two alternating, random colors.

**6.2** Create a program that draws 10 random filled shapes in random colors, positions and sizes (Fig. 6.14). Method `paintComponent` should contain a loop that iterates 10 times. In each iteration, the loop should determine whether to draw a filled rectangle or an oval, create a random color and choose coordinates and dimensions at random. The coordinates should be chosen based on the panel's width and height. Lengths of sides should be limited to half the width or height of the window.

**Fig. 6.14** | Randomly generated shapes.

## 6.14 Wrap-Up

In this chapter, you learned more about method declarations. You also learned the difference between non-static and static methods and how to call static methods by preceding the method name with the name of the class in which it appears and the dot (`.`) separator. You learned how to use operators `+` and `+=` to perform string concatenations. We discussed how the method-call stack and activation records keep track of the methods that have been called and where each method must return to when it completes its task. We also discussed Java's promotion rules for converting implicitly between primitive types and how to perform explicit conversions with cast operators. Next, you learned about some of the commonly used packages in the Java API.

You saw how to declare named constants using both enum types and `public static final` variables. You used class `Random` to generate random numbers for simulations. You also learned about the scope of fields and local variables in a class. Finally, you learned that multiple methods in one class can be overloaded by providing methods with the same name and different signatures. Such methods can be used to perform the same or similar tasks using different types or different numbers of parameters.

In Chapter 7, you'll learn how to maintain lists and tables of data in arrays. You'll see a more elegant implementation of the application that rolls a die 6,000,000 times and two enhanced versions of our `GradeBook` case study that you studied in Chapters 3–5. You'll also learn how to access an application's command-line arguments that are passed to method `main` when an application begins execution.

## Summary

### Section 6.1 Introduction

- Experience has shown that the best way to develop and maintain a large program is to construct it from small, simple pieces, or modules. This technique is called divide and conquer (p. 198).

### Section 6.2 Program Modules in Java

- Methods are declared within classes. Classes are typically grouped into packages so they can be imported and reused.
- Methods allow you to modularize a program by separating its tasks into self-contained units. The statements in a method are written only once and hidden from other methods.
- Using existing methods as building blocks to create new programs is a form of software reusability (p. 199) that allows you to avoid repeating code within a program.

### Section 6.3 *static* Methods, *static* Fields and *Class Math*

- A method call specifies the name of the method to call and provides the arguments that the called method requires to perform its task. When the method call completes, the method returns either a result, or simply control, to its caller.
- A class may contain *static* methods to perform common tasks that do not require an object of the class. Any data a *static* method might require to perform its tasks can be sent to the method as arguments in a method call. A *static* method is called by specifying the name of the class in which the method is declared followed by a dot (.) and the method name, as in

*ClassName.methodName( arguments )*

- Class *Math* provides *static* methods for performing common mathematical calculations.
- The constant *Math.PI* (p. 201; 3.141592653589793) is the ratio of a circle's circumference to its diameter. The constant *Math.E* (p. 201; 2.718281828459045) is the base value for natural logarithms (calculated with *static Math* method *log*).
- *Math.PI* and *Math.E* are declared with the modifiers *public*, *final* and *static*. Making them *public* allows you to use these fields in your own classes. A field declared with keyword *final* (p. 201) is constant—its value cannot be changed after it's initialized. Both *PI* and *E* are declared *final* because their values never change. Making these fields *static* allows them to be accessed via the class name *Math* and a dot (.) separator, just like class *Math*'s methods.
- All the objects of a class share one copy of the class's *static* fields. Together the class variables (p. 201) and instance variables represent the fields of a class.
- When you execute the Java Virtual Machine (JVM) with the *java* command, the JVM loads the class you specify and uses that class name to invoke method *main*. You can specify additional command-line arguments (p. 202) that the JVM will pass to your application.
- You can place a *main* method in every class you declare—only the *main* method in the class you use to execute the application will be called by the *java* command.

### Section 6.4 Declaring Methods with Multiple Parameters

- When a method is called, the program makes a copy of the method's argument values and assigns them to the method's corresponding parameters. When program control returns to the point in the program where the method was called, the method's parameters are removed from memory.
- A method can return at most one value, but the returned value could be a reference to an object that contains many values.
- Variables should be declared as fields of a class only if they're required for use in more than one method of the class or if the program should save their values between calls to the class's methods.

- When a method has more than one parameter, the parameters are specified as a comma-separated list. There must be one argument in the method call for each parameter in the method declaration. Also, each argument must be consistent with the type of the corresponding parameter. If a method does not accept arguments, the parameter list is empty.
- Strings can be concatenated (p. 204) using operator `+`, which places the characters of the right operand at the end of those in the left operand.
- Every primitive value and object in Java has a `String` representation. When an object is concatenated with a `String`, the object is converted to a `String`, then the two `Strings` are concatenated.
- If a `boolean` is concatenated with a `String`, the word `"true"` or the word `"false"` is used to represent the `boolean` value.
- All objects in Java have a special method named `toString` that returns a `String` representation of the object's contents. When an object is concatenated with a `String`, the JVM implicitly calls the object's `toString` method to obtain the string representation of the object.
- You can break large `String` literals into several smaller `Strings` and place them on multiple lines of code for readability, then reassemble the `Strings` using concatenation.

### Section 6.5 Notes on Declaring and Using Methods

- There are three ways to call a method—using a method name by itself to call another method of the same class; using a variable that contains a reference to an object, followed by a dot (`.`) and the method name to call a method of the referenced object; and using the class name and a dot (`.`) to call a `static` method of a class.
- There are three ways to return control to a statement that calls a method. If the method does not return a result, control returns when the program flow reaches the method-ending right brace or when the statement

```
return;
```

is executed. If the method returns a result, the statement

```
return expression;
```

evaluates the *expression*, then immediately returns the resulting value to the caller.

### Section 6.6 Method-Call Stack and Activation Records

- Stacks (p. 206) are known as last-in, first-out (LIFO) data structures—the last item pushed (inserted) on the stack is the first item popped (removed) from the stack.
- A called method must know how to return to its caller, so the return address of the calling method is pushed onto the program-execution stack when the method is called. If a series of method calls occurs, the successive return addresses are pushed onto the stack in last-in, first-out order so that the last method to execute will be the first to return to its caller.
- The program-execution stack (p. 207) contains the memory for the local variables used in each invocation of a method during a program's execution. This data is known as the method call's activation record or stack frame. When a method call is made, the activation record for that method call is pushed onto the program-execution stack. When the method returns to its caller, its activation record call is popped off the stack and the local variables are no longer known to the program.
- If there are more method calls than can have their activation records stored on the program-execution stack, an error known as a stack overflow (p. 207) occurs. The application will compile correctly, but its execution causes a stack overflow.

### Section 6.7 Argument Promotion and Casting

- Argument promotion (p. 207) converts an argument's value to the type that the method expects to receive in its corresponding parameter.

- Promotion rules (p. 207) apply to expressions containing values of two or more primitive types and to primitive-type values passed as arguments to methods. Each value is promoted to the “highest” type in the expression. In cases where information may be lost due to conversion, the Java compiler requires you to use a cast operator to explicitly force the conversion to occur.

### Section 6.9 Case Study: Random-Number Generation

- Objects of class `Random` (p. 210; package `java.util`) can produce random values. `Math` method `random` can produce `double` values in the range  $0.0 \leq x < 1.0$ , where  $x$  is the value returned.
- `Random` method `nextInt` (p. 210) generates a random `int` value in the range  $-2,147,483,648$  to  $+2,147,483,647$ . The values returned by `nextInt` are actually pseudorandom numbers (p. 210)—a sequence of values produced by a complex mathematical calculation. That calculation uses the current time of day to seed (p. 211) the random-number generator such that each execution of a program yields a different sequence of random values.
- Class `Random` provides another version of method `nextInt` that receives an `int` argument and returns a value from 0 up to, but not including, the argument’s value.
- Random numbers in a range (p. 211) can be generated with

```
number = shiftingValue + randomNumbers.nextInt( scalingFactor );
```

where *shiftingValue* specifies the first number in the desired range of consecutive integers, and *scalingFactor* specifies how many numbers are in the range.

- Random numbers can be chosen from nonconsecutive integer ranges, as in

```
number = shiftingValue +
        differenceBetweenValues * randomNumbers.nextInt( scalingFactor );
```

where *shiftingValue* specifies the first number in the range of values, *differenceBetweenValues* represents the difference between consecutive numbers in the sequence and *scalingFactor* specifies how many numbers are in the range.

- For debugging, it’s sometimes useful to repeat the sequence of pseudorandom numbers during each program execution. To do so, pass a `long` integer value to the `Random` object’s constructor. Using the same seed every time the program executes, produces the same sequence of numbers.

### Section 6.10 Case Study: A Game of Chance; Introducing Enumerations

- An enumeration (p. 218) is introduced by the keyword `enum` and a type name. As with any class, braces (`{` and `}`) delimit the body of an `enum` declaration. Inside the braces is a comma-separated list of enumeration constants, each representing a unique value. The identifiers in an `enum` must be unique. Variables of an `enum` type can be assigned only constants of that `enum` type.
- Constants can also be declared as `public final static` variables. Such constants are declared by convention with all capital letters to make them stand out in the program.

### Section 6.11 Scope of Declarations

- Scope (p. 220) is the portion of the program in which an entity, such as a variable or a method, can be referred to by its name. Such an entity is said to be “in scope” for that portion of the program.
- The scope of a parameter declaration is the body of the method in which the declaration appears.
- The scope of a local-variable declaration is from the point at which the declaration appears to the end of that block.
- The scope of a local-variable declaration that appears in the initialization section of a `for` statement’s header is the body of the `for` statement and the other expressions in the header.
- The scope of a method or field of a class is the entire body of the class. This enables a class’s methods to use simple names to call the class’s other methods and to access the class’s fields.

- Any block may contain variable declarations. If a local variable or parameter in a method has the same name as a field, the field is shadowed (p. 220) until the block terminates execution.

### Section 6.12 Method Overloading

- Java allows overloaded methods (p. 222) in a class, as long as the methods have different sets of parameters (determined by the number, order and types of the parameters).
- Overloaded methods are distinguished by their signatures (p. 223)—combinations of the methods' names and the number, types and order of their parameters.

## Self-Review Exercises

- 6.1** Fill in the blanks in each of the following statements:
- A method is invoked with a(n) \_\_\_\_\_.
  - A variable known only within the method in which it's declared is called a(n) \_\_\_\_\_.
  - The \_\_\_\_\_ statement in a called method can be used to pass the value of an expression back to the calling method.
  - The keyword \_\_\_\_\_ indicates that a method does not return a value.
  - Data can be added or removed only from the \_\_\_\_\_ of a stack.
  - Stacks are known as \_\_\_\_\_ data structures; the last item pushed (inserted) on the stack is the first item popped (removed) from the stack.
  - The three ways to return control from a called method to a caller are \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - An object of class \_\_\_\_\_ produces random numbers.
  - The program-execution stack contains the memory for local variables on each invocation of a method during a program's execution. This data, stored as a portion of the program-execution stack, is known as the \_\_\_\_\_ or \_\_\_\_\_ of the method call.
  - If there are more method calls than can be stored on the program-execution stack, an error known as a(n) \_\_\_\_\_ occurs.
  - The \_\_\_\_\_ of a declaration is the portion of a program that can refer to the entity in the declaration by name.
  - It's possible to have several methods with the same name that each operate on different types or numbers of arguments. This feature is called method \_\_\_\_\_.
  - The program-execution stack is also referred to as the \_\_\_\_\_ stack.
- 6.2** For the class Craps in Fig. 6.8, state the scope of each of the following entities:
- the variable `randomNumbers`.
  - the variable `die1`.
  - the method `rollDice`.
  - the method `main`.
  - the variable `sumOfDice`.
- 6.3** Write an application that tests whether the examples of the Math class method calls shown in Fig. 6.2 actually produce the indicated results.
- 6.4** Give the method header for each of the following methods:
- Method `hypotenuse`, which takes two double-precision, floating-point arguments `side1` and `side2` and returns a double-precision, floating-point result.
  - Method `smallest`, which takes three integers `x`, `y` and `z` and returns an integer.
  - Method `instructions`, which does not take any arguments and does not return a value. [Note: Such methods are commonly used to display instructions to a user.]
  - Method `intToFloat`, which takes integer argument `number` and returns a `float`.
- 6.5** Find the error in each of the following program segments. Explain how to correct the error.

```

a) void g()
{
    System.out.println( "Inside method g" );

    void h()
    {
        System.out.println( "Inside method h" );
    }
}

b) int sum( int x, int y )
{
    int result;
    result = x + y;
}

c) void f( float a );
{
    float a;
    System.out.println( a );
}

d) void product()
{
    int a = 6, b = 5, c = 4, result;
    result = a * b * c;
    System.out.printf( "Result is %d\n", result );
    return result;
}

```

**6.6** Write a complete Java application to prompt the user for the double radius of a sphere, and call method `sphereVolume` to calculate and display the volume of the sphere. Use the following statement to calculate the volume:

```
double volume = ( 4.0 / 3.0 ) * Math.PI * Math.pow( radius, 3 )
```

## Answers to Self-Review Exercises

**6.1** a) method call. b) local variable. c) return. d) void. e) top. f) last-in, first-out (LIFO). g) return; or return *expression*; or encountering the closing right brace of a method. h) Random. i) activation record, stack frame. j) stack overflow. k) scope. l) method overloading. m) method call.

**6.2** a) class body. b) block that defines method `rollDice`'s body. c) class body. d) class body. e) block that defines method `main`'s body.

**6.3** The following solution demonstrates the `Math` class methods in Fig. 6.2:

---

```

1 // Exercise 6.3: MathTest.java
2 // Testing the Math class methods.
3
4 public class MathTest
5 {
6     public static void main( String[] args )
7     {
8         System.out.printf( "Math.abs( 23.7 ) = %f\n", Math.abs( 23.7 ) );
9         System.out.printf( "Math.abs( 0.0 ) = %f\n", Math.abs( 0.0 ) );
10        System.out.printf( "Math.abs( -23.7 ) = %f\n", Math.abs( -23.7 ) );
11        System.out.printf( "Math.ceil( 9.2 ) = %f\n", Math.ceil( 9.2 ) );

```

```

12     System.out.printf( "Math.ceil( -9.8 ) = %f\n", Math.ceil( -9.8 ) );
13     System.out.printf( "Math.cos( 0.0 ) = %f\n", Math.cos( 0.0 ) );
14     System.out.printf( "Math.exp( 1.0 ) = %f\n", Math.exp( 1.0 ) );
15     System.out.printf( "Math.exp( 2.0 ) = %f\n", Math.exp( 2.0 ) );
16     System.out.printf( "Math.floor( 9.2 ) = %f\n", Math.floor( 9.2 ) );
17     System.out.printf( "Math.floor( -9.8 ) = %f\n",
18         Math.floor( -9.8 ) );
19     System.out.printf( "Math.log( Math.E ) = %f\n",
20         Math.log( Math.E ) );
21     System.out.printf( "Math.log( Math.E * Math.E ) = %f\n",
22         Math.log( Math.E * Math.E ) );
23     System.out.printf( "Math.max( 2.3, 12.7 ) = %f\n",
24         Math.max( 2.3, 12.7 ) );
25     System.out.printf( "Math.max( -2.3, -12.7 ) = %f\n",
26         Math.max( -2.3, -12.7 ) );
27     System.out.printf( "Math.min( 2.3, 12.7 ) = %f\n",
28         Math.min( 2.3, 12.7 ) );
29     System.out.printf( "Math.min( -2.3, -12.7 ) = %f\n",
30         Math.min( -2.3, -12.7 ) );
31     System.out.printf( "Math.pow( 2.0, 7.0 ) = %f\n",
32         Math.pow( 2.0, 7.0 ) );
33     System.out.printf( "Math.pow( 9.0, 0.5 ) = %f\n",
34         Math.pow( 9.0, 0.5 ) );
35     System.out.printf( "Math.sin( 0.0 ) = %f\n", Math.sin( 0.0 ) );
36     System.out.printf( "Math.sqrt( 900.0 ) = %f\n",
37         Math.sqrt( 900.0 ) );
38     System.out.printf( "Math.tan( 0.0 ) = %f\n", Math.tan( 0.0 ) );
39 } // end main
40 } // end class MathTest

```

```

Math.abs( 23.7 ) = 23.700000

- 6.4**
- `double` hypotenuse( `double` side1, `double` side2 )
  - `int` smallest( `int` x, `int` y, `int` z )
  - `void` instructions()
  - `float` intToFloat( `int` number )
- 6.5**
- Error: Method h is declared within method g.  
Correction: Move the declaration of h outside the declaration of g.
  - Error: The method is supposed to return an integer, but does not.  
Correction: Delete the variable result, and place the statement

```
return x + y;
```

in the method, or add the following statement at the end of the method body:

```
return result;
```

- c) Error: The semicolon after the right parenthesis of the parameter list is incorrect, and the parameter `a` should not be redeclared in the method.

Correction: Delete the semicolon after the right parenthesis of the parameter list, and delete the declaration `float a;`

- d) Error: The method returns a value when it's not supposed to.

Correction: Change the return type from `void` to `int`.

**6.6** The following solution calculates the volume of a sphere, using the radius entered by the user:

```

1 // Exercise 6.6: Sphere.java
2 // Calculate the volume of a sphere.
3 import java.util.Scanner;
4
5 public class Sphere
6 {
7     // obtain radius from user and display volume of sphere
8     public static void main( String[] args )
9     {
10        Scanner input = new Scanner( System.in );
11
12        System.out.print( "Enter radius of sphere: " );
13        double radius = input.nextDouble();
14
15        System.out.printf( "Volume is %f\n", sphereVolume( radius ) );
16    } // end method determineSphereVolume
17
18    // calculate and return sphere volume
19    public static double sphereVolume( double radius )
20    {
21        double volume = ( 4.0 / 3.0 ) * Math.PI * Math.pow( radius, 3 );
22        return volume;
23    } // end method sphereVolume
24 } // end class Sphere

```

```

Enter radius of sphere: 4
Volume is 268.082573

```

## Exercises

**6.7** What is the value of `x` after each of the following statements is executed?

- `x = Math.abs( 7.5 );`
- `x = Math.floor( 7.5 );`
- `x = Math.abs( 0.0 );`
- `x = Math.ceil( 0.0 );`
- `x = Math.abs( -6.4 );`
- `x = Math.ceil( -6.4 );`
- `x = Math.ceil( -Math.abs( -8 + Math.floor( -5.5 ) ) );`

**6.8** (*Parking Charges*) A parking garage charges a \$2.00 minimum fee to park for up to three hours. The garage charges an additional \$0.50 per hour for each hour *or part thereof* in excess of three hours. The maximum charge for any given 24-hour period is \$10.00. Assume that no car parks for longer than 24 hours at a time. Write an application that calculates and displays the parking charges for each customer who parked in the garage yesterday. You should enter the hours parked for each

customer. The program should display the charge for the current customer and should calculate and display the running total of yesterday's receipts. It should use the method `calculateCharges` to determine the charge for each customer.

**6.9 (Rounding Numbers)** `Math.floor` can be used to round values to the nearest integer—e.g.,

```
y = Math.floor( x + 0.5 );
```

will round the number  $x$  to the nearest integer and assign the result to  $y$ . Write an application that reads `double` values and uses the preceding statement to round each of the numbers to the nearest integer. For each number processed, display both the original number and the rounded number.

**6.10 (Rounding Numbers)** To round numbers to specific decimal places, use a statement like

```
y = Math.floor( x * 10 + 0.5 ) / 10;
```

which rounds  $x$  to the tenths position (i.e., the first position to the right of the decimal point), or

```
y = Math.floor( x * 100 + 0.5 ) / 100;
```

which rounds  $x$  to the hundredths position (i.e., the second position to the right of the decimal point). Write an application that defines four methods for rounding a number  $x$  in various ways:

- `roundToInteger( number )`
- `roundToTenths( number )`
- `roundToHundredths( number )`
- `roundToThousandths( number )`

For each value read, your program should display the original value, the number rounded to the nearest integer, the number rounded to the nearest tenth, the number rounded to the nearest hundredth and the number rounded to the nearest thousandth.

**6.11** Answer each of the following questions:

- What does it mean to choose numbers “at random”?
- Why is the `nextInt` method of class `Random` useful for simulating games of chance?
- Why is it often necessary to scale or shift the values produced by a `Random` object?
- Why is computerized simulation of real-world situations a useful technique?

**6.12** Write statements that assign random integers to the variable  $n$  in the following ranges:

- $1 \leq n \leq 2$ .
- $1 \leq n \leq 100$ .
- $0 \leq n \leq 9$ .
- $1000 \leq n \leq 1112$ .
- $-1 \leq n \leq 1$ .
- $-3 \leq n \leq 11$ .

**6.13** Write statements that will display a random number from each of the following sets:

- 2, 4, 6, 8, 10.
- 3, 5, 7, 9, 11.
- 6, 10, 14, 18, 22.

**6.14 (Exponentiation)** Write a method `integerPower(base, exponent)` that returns the value of  $base^{exponent}$

For example, `integerPower(3, 4)` calculates  $3^4$  (or  $3 * 3 * 3 * 3$ ). Assume that `exponent` is a positive, nonzero integer and that `base` is an integer. Use a `for` or `while` statement to control the calculation. Do not use any `Math` class methods. Incorporate this method into an application that reads integer values for `base` and `exponent` and performs the calculation with the `integerPower` method.

**6.15 (Hypotenuse Calculations)** Define a method `hypotenuse` that calculates the hypotenuse of a right triangle when the lengths of the other two sides are given. The method should take two ar-

guments of type `double` and return the hypotenuse as a `double`. Incorporate this method into an application that reads values for `side1` and `side2` and performs the calculation with the hypotenuse method. Use `Math` methods `pow` and `sqrt` to determine the length of the hypotenuse for each of the triangles in Fig. 6.15. [Note: Class `Math` also provides method `hypot` to perform this calculation.]

| Triangle | Side 1 | Side 2 |
|----------|--------|--------|
| 1        | 3.0    | 4.0    |
| 2        | 5.0    | 12.0   |
| 3        | 8.0    | 15.0   |

**Fig. 6.15** | Values for the sides of triangles in Exercise 6.15.

**6.16** (*Multiples*) Write a method `isMultiple` that determines, for a pair of integers, whether the second integer is a multiple of the first. The method should take two integer arguments and return `true` if the second is a multiple of the first and `false` otherwise. [Hint: Use the remainder operator.] Incorporate this method into an application that inputs a series of pairs of integers (one pair at a time) and determines whether the second value in each pair is a multiple of the first.

**6.17** (*Even or Odd*) Write a method `isEven` that uses the remainder operator (`%`) to determine whether an integer is even. The method should take an integer argument and return `true` if the integer is even and `false` otherwise. Incorporate this method into an application that inputs a sequence of integers (one at a time) and determines whether each is even or odd.

**6.18** (*Displaying a Square of Asterisks*) Write a method `squareOfAsterisks` that displays a solid square (the same number of rows and columns) of asterisks whose side is specified in integer parameter `side`. For example, if `side` is 4, the method should display

```
****
****
****
****
```

Incorporate this method into an application that reads an integer value for `side` from the user and outputs the asterisks with the `squareOfAsterisks` method.

**6.19** (*Displaying a Square of Any Character*) Modify the method created in Exercise 6.18 to receive a second parameter of type `char` called `fillCharacter`. Form the square using the `char` provided as an argument. Thus, if `side` is 5 and `fillCharacter` is `#`, the method should display

```
#####
#####
#####
#####
#####
```

Use the following statement (in which `input` is a `Scanner` object) to read a character from the user at the keyboard:

```
char fill = input.next().charAt( 0 );
```

**6.20** (*Circle Area*) Write an application that prompts the user for the radius of a circle and uses a method called `circleArea` to calculate the area of the circle.

**6.21** (*Separating Digits*) Write methods that accomplish each of the following tasks:

- Calculate the integer part of the quotient when integer `a` is divided by integer `b`.
- Calculate the integer remainder when integer `a` is divided by integer `b`.

- c) Use the methods developed in parts (a) and (b) to write a method `displayDigits` that receives an integer between 1 and 99999 and displays it as a sequence of digits, separating each pair of digits by two spaces. For example, the integer 4562 should appear as

```
4 5 6 2
```

Incorporate the methods into an application that inputs an integer and calls `displayDigits` by passing the method the integer entered. Display the results.

**6.22** (*Temperature Conversions*) Implement the following integer methods:

- a) Method `celsius` returns the Celsius equivalent of a Fahrenheit temperature, using the calculation

```
celsius = 5.0 / 9.0 * ( fahrenheit - 32 );
```

- b) Method `fahrenheit` returns the Fahrenheit equivalent of a Celsius temperature, using the calculation

```
fahrenheit = 9.0 / 5.0 * celsius + 32;
```

- c) Use the methods from parts (a) and (b) to write an application that enables the user either to enter a Fahrenheit temperature and display the Celsius equivalent or to enter a Celsius temperature and display the Fahrenheit equivalent.

**6.23** (*Find the Minimum*) Write a method `minimum3` that returns the smallest of three floating-point numbers. Use the `Math.min` method to implement `minimum3`. Incorporate the method into an application that reads three values from the user, determines the smallest value and displays the result.

**6.24** (*Perfect Numbers*) An integer number is said to be a *perfect number* if its factors, including 1 (but not the number itself), sum to the number. For example, 6 is a perfect number, because  $6 = 1 + 2 + 3$ . Write a method `isPerfect` that determines if parameter `number` is a perfect number. Use this method in an application that displays all the perfect numbers between 1 and 1000. Display the factors of each perfect number to confirm that the number is indeed perfect. Challenge the computing power of your computer by testing numbers much larger than 1000. Display the results.

**6.25** (*Prime Numbers*) A positive integer is *prime* if it's divisible by only 1 and itself. For example, 2, 3, 5 and 7 are prime, but 4, 6, 8 and 9 are not. The number 1, by definition, is not prime.

- Write a method that determines whether a number is prime.
- Use this method in an application that determines and displays all the prime numbers less than 10,000. How many numbers up to 10,000 do you have to test to ensure that you've found all the primes?
- Initially, you might think that  $n/2$  is the upper limit for which you must test to see whether a number  $n$  is prime, but you need only go as high as the square root of  $n$ . Rewrite the program, and run it both ways.

**6.26** (*Reversing Digits*) Write a method that takes an integer value and returns the number with its digits reversed. For example, given the number 7631, the method should return 1367. Incorporate the method into an application that reads a value from the user and displays the result.

**6.27** (*Greatest Common Divisor*) The *greatest common divisor* (*GCD*) of two integers is the largest integer that evenly divides each of the two numbers. Write a method `gcd` that returns the greatest common divisor of two integers. [*Hint:* You might want to use Euclid's algorithm. You can find information about it at [en.wikipedia.org/wiki/Euclidean\\_algorithm](http://en.wikipedia.org/wiki/Euclidean_algorithm).] Incorporate the method into an application that reads two values from the user and displays the result.

**6.28** Write a method `qualityPoints` that inputs a student's average and returns 4 if it's 90–100, 3 if 80–89, 2 if 70–79, 1 if 60–69 and 0 if lower than 60. Incorporate the method into an application that reads a value from the user and displays the result.

**6.29** (*Coin Tossing*) Write an application that simulates coin tossing. Let the program toss a coin each time the user chooses the “Toss Coin” menu option. Count the number of times each side of the coin appears. Display the results. The program should call a separate method `flip` that takes no arguments and returns a value from a `Coin` enum (`HEADS` and `TAILS`). [Note: If the program realistically simulates coin tossing, each side of the coin should appear approximately half the time.]

**6.30** (*Guess the Number*) Write an application that plays “guess the number” as follows: Your program chooses the number to be guessed by selecting a random integer in the range 1 to 1000. The application displays the prompt `Guess a number between 1 and 1000`. The player inputs a first guess. If the player's guess is incorrect, your program should display `Too high. Try again.` or `Too low. Try again.` to help the player “zero in” on the correct answer. The program should prompt the user for the next guess. When the user enters the correct answer, display `Congratulations. You guessed the number!`, and allow the user to choose whether to play again. [Note: The guessing technique employed in this problem is similar to a binary search, which is discussed in Chapter 19, Searching, Sorting and Big O.]

**6.31** (*Guess the Number Modification*) Modify the program of Exercise 6.30 to count the number of guesses the player makes. If the number is 10 or fewer, display `Either you know the secret or you got lucky!` If the player guesses the number in 10 tries, display `Aha! You know the secret!` If the player makes more than 10 guesses, display `You should be able to do better! Why should it take no more than 10 guesses? Well, with each “good guess,” the player should be able to eliminate half of the numbers, then half of the remaining numbers, and so on.`

**6.32** (*Distance Between Points*) Write method `distance` to calculate the distance between two points  $(x1, y1)$  and  $(x2, y2)$ . All numbers and return values should be of type `double`. Incorporate this method into an application that enables the user to enter the coordinates of the points.

**6.33** (*Craps Game Modification*) Modify the craps program of Fig. 6.8 to allow wagering. Initialize variable `bankBalance` to 1000 dollars. Prompt the player to enter a wager. Check that wager is less than or equal to `bankBalance`, and if it's not, have the user reenter `wager` until a valid wager is entered. Then, run one game of craps. If the player wins, increase `bankBalance` by `wager` and display the new `bankBalance`. If the player loses, decrease `bankBalance` by `wager`, display the new `bankBalance`, check whether `bankBalance` has become zero and, if so, display the message `Sorry. You busted!` As the game progresses, display various messages to create some “chatter,” such as `Oh, you're going for broke, huh?` or `Aw c'mon, take a chance!` or `You're up big. Now's the time to cash in your chips!`. Implement the “chatter” as a separate method that randomly chooses the string to display.

**6.34** (*Table of Binary, Octal and Hexadecimal Numbers*) Write an application that displays a table of the binary, octal and hexadecimal equivalents of the decimal numbers in the range 1 through 256. If you aren't familiar with these number systems, read Appendix H first.

## Making a Difference

As computer costs decline, it becomes feasible for every student, regardless of economic circumstance, to have a computer and use it in school. This creates exciting possibilities for improving the educational experience of all students worldwide, as suggested by the next five exercises. [Note: Check out initiatives such as the One Laptop Per Child Project ([www.laptop.org](http://www.laptop.org)). Also, research “green” laptops—what are some key “going green” characteristics of these devices? Look into the Electronic Product Environmental Assessment Tool ([www.epeat.net](http://www.epeat.net)), which can help you assess the “greenness” of desktops, notebooks and monitors to help you decide which products to purchase.]

**6.35** (*Computer-Assisted Instruction*) The use of computers in education is referred to as *computer-assisted instruction* (CAI). Write a program that will help an elementary school student learn

multiplication. Use a Random object to produce two positive one-digit integers. The program should then prompt the user with a question, such as

How much is 6 times 7?

The student then inputs the answer. Next, the program checks the student's answer. If it's correct, display the message "Very good!" and ask another multiplication question. If the answer is wrong, display the message "No. Please try again." and let the student try the same question repeatedly until the student finally gets it right. A separate method should be used to generate each new question. This method should be called once when the application begins execution and each time the user answers the question correctly.

**6.36** (*Computer-Assisted Instruction: Reducing Student Fatigue*) One problem in CAI environments is student fatigue. This can be reduced by varying the computer's responses to hold the student's attention. Modify the program of Exercise 6.35 so that various comments are displayed for each answer as follows:

Possible responses to a correct answer:

Very good!  
Excellent!  
Nice work!  
Keep up the good work!

Possible responses to an incorrect answer:

No. Please try again.  
Wrong. Try once more.  
Don't give up!  
No. Keep trying.

Use random-number generation to choose a number from 1 to 4 that will be used to select one of the four appropriate responses to each correct or incorrect answer. Use a switch statement to issue the responses.

**6.37** (*Computer-Assisted Instruction: Monitoring Student Performance*) More sophisticated computer-assisted instruction systems monitor the student's performance over a period of time. The decision to begin a new topic is often based on the student's success with previous topics. Modify the program of Exercise 6.36 to count the number of correct and incorrect responses typed by the student. After the student types 10 answers, your program should calculate the percentage that are correct. If the percentage is lower than 75%, display "Please ask your teacher for extra help.", then reset the program so another student can try it. If the percentage is 75% or higher, display "Congratulations, you are ready to go to the next level!", then reset the program so another student can try it.

**6.38** (*Computer-Assisted Instruction: Difficulty Levels*) Exercise 6.35 through Exercise 6.37 developed a computer-assisted instruction program to help teach an elementary school student multiplication. Modify the program to allow the user to enter a difficulty level. At a difficulty level of 1, the program should use only single-digit numbers in the problems; at a difficulty level of 2, numbers as large as two digits, and so on.

**6.39** (*Computer-Assisted Instruction: Varying the Types of Problems*) Modify the program of Exercise 6.38 to allow the user to pick a type of arithmetic problem to study. An option of 1 means addition problems only, 2 means subtraction problems only, 3 means multiplication problems only, 4 means division problems only and 5 means a random mixture of all these types.

# 7

## Arrays and ArrayLists

*Begin at the beginning, ... and go on till you come to the end: then stop.*

—Lewis Carroll

*Now go, write it before them in a table, and note it in a book.*

—Isaiah 30:8

*To go beyond is as wrong as to fall short.*

—Confucius 1

### Objectives

In this chapter you'll learn:

- What arrays are.
- To use arrays to store data in and retrieve data from lists and tables of values.
- To declare arrays, initialize arrays and refer to individual elements of arrays.
- To iterate through arrays with the enhanced `for` statement.
- To pass arrays to methods.
- To declare and manipulate multidimensional arrays.
- To use variable-length argument lists.
- To read command-line arguments into a program.
- To perform common array manipulations with the methods of class `Arrays`.
- To use class `ArrayList` to manipulate a dynamically resizable array-like data structure.

- |                                                                                    |                                                                                    |

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Special Section: Building Your Own Computer | Making a Difference*

## 7.1 Introduction

This chapter introduces **data structures**—collections of related data items. **Arrays** are data structures consisting of related data items of the same type. Arrays make it convenient to process related groups of values. Arrays remain the same length once they’re created, although an array variable may be reassigned such that it refers to a new array of a different length. We study data structures in depth in Chapters 20–22.

After discussing how arrays are declared, created and initialized, we present practical examples that demonstrate common array manipulations. We introduce Java’s exception-handling mechanism and use it to allow a program to continue executing when the program attempts to access an array element that does not exist. We also present a case study that examines how arrays can help simulate the shuffling and dealing of playing cards in a card-game application. We introduce Java’s enhanced `for` statement, which allows a program to access the data in an array more easily than does the counter-controlled `for` statement presented in Section 5.3. We enhance the `GradeBook` case study from Chapters 3–5. In particular, we use arrays to enable the class to maintain a set of grades *in memory* and analyze student grades from multiple exams. We show how to use variable-length argument lists to create methods that can be called with varying numbers of arguments, and we demonstrate how to process command-line arguments in method `main`. Next, we present some common array manipulations with `static` methods of class `Arrays` from the `java.util` package.

Although commonly used, arrays have limited capabilities. For instance, you must specify an array’s size, and if at execution time you wish to modify it, you must do so manually by creating a new array. At the end of this chapter, we introduce one of Java’s prebuilt data structures from the Java API’s collection classes. These offer greater capabilities than traditional arrays. They’re reusable, reliable, powerful and efficient. We focus on the `ArrayList` collection. `ArrayLists` are similar to arrays but provide additional functionality, such as **dynamic resizing**—they automatically increase their size at execution time to accommodate additional elements.

## 7.2 Arrays

An array is a group of variables (called **elements** or **components**) containing values that all have the same type. Arrays are *objects*, so they're considered reference types. As you'll soon see, what we typically think of as an array is actually a reference to an array object in memory. The *elements* of an array can be either primitive types or reference types (including arrays, as we'll see in Section 7.9). To refer to a particular element in an array, we specify the name of the reference to the array and the *position number* of the element in the array. The position number of the element is called the element's **index** or **subscript**.

Figure 7.1 shows a logical representation of an integer array called *c*. This array contains 12 elements. A program refers to any one of these elements with an **array-access expression** that includes the name of the array followed by the index of the particular element in **square brackets** (`[]`). The first element in every array has **index zero** and is sometimes called the **zeroth element**. Thus, the elements of array *c* are `c[0]`, `c[1]`, `c[2]` and so on. The highest index in array *c* is 11, which is 1 less than 12—the number of elements in the array. Array names follow the same conventions as other variable names.

|                                                  |                      |      |
|--------------------------------------------------|----------------------|------|
| Name of array (c) →                              | <code>c[ 0 ]</code>  | -45  |
|                                                  | <code>c[ 1 ]</code>  | 6    |
|                                                  | <code>c[ 2 ]</code>  | 0    |
|                                                  | <code>c[ 3 ]</code>  | 72   |
|                                                  | <code>c[ 4 ]</code>  | 1543 |
|                                                  | <code>c[ 5 ]</code>  | -89  |
|                                                  | <code>c[ 6 ]</code>  | 0    |
|                                                  | <code>c[ 7 ]</code>  | 62   |
|                                                  | <code>c[ 8 ]</code>  | -3   |
|                                                  | <code>c[ 9 ]</code>  | 1    |
|                                                  | <code>c[ 10 ]</code> | 6453 |
| Index (or subscript) of the element in array c → | <code>c[ 11 ]</code> | 78   |

**Fig. 7.1** | A 12-element array.

An index must be a nonnegative integer. A program can use an expression as an index. For example, if we assume that variable *a* is 5 and variable *b* is 6, then the statement

```
c[ a + b ] += 2;
```

adds 2 to array element `c[11]`. An indexed array name is an array-access expression, which can be used on the left side of an assignment to place a new value into an array element.

### Common Programming Error 7.1

*An index must be an `int` value or a value of a type that can be promoted to `int`—namely, `byte`, `short` or `char`, but not `long`; otherwise, a compilation error occurs.*

Let's examine array *c* in Fig. 7.1 more closely. The **name** of the array is *c*. Every array object knows its own length and stores it in a **length instance variable**. The expression

`c.length` accesses array `c`'s `length` field to determine the length of the array. Even though the `length` instance variable of an array is `public`, it cannot be changed because it's a `final` variable. This array's 12 elements are referred to as `c[0]`, `c[1]`, `c[2]`, ..., `c[11]`. The value of `c[0]` is `-45`, the value of `c[1]` is `6`, the value of `c[2]` is `0`, the value of `c[7]` is `62` and the value of `c[11]` is `78`. To calculate the sum of the values contained in the first three elements of array `c` and store the result in variable `sum`, we would write

```
sum = c[ 0 ] + c[ 1 ] + c[ 2 ];
```

To divide the value of `c[6]` by 2 and assign the result to the variable `x`, we would write

```
x = c[ 6 ] / 2;
```

## 7.3 Declaring and Creating Arrays

Array objects occupy space in memory. Like other objects, arrays are created with keyword `new`. To create an array object, you specify the type of the array elements and the number of elements as part of an **array-creation expression** that uses keyword `new`. Such an expression returns a reference that can be stored in an array variable. The following declaration and array-creation expression create an array object containing 12 `int` elements and store the array's reference in array variable `c`:

```
int[] c = new int[ 12 ];
```

This expression can be used to create the array shown in Fig. 7.1. When an array is created, each element of the array receives a default value—zero for the numeric primitive-type elements, `false` for `boolean` elements and `null` for references. As you'll soon see, you can provide nondefault initial element values when you create an array.

Creating the array in Fig. 7.1 can also be performed in two steps as follows:

```
int[] c; // declare the array variable
c = new int[ 12 ]; // create the array; assign to array variable
```

In the declaration, the square brackets following the type indicate that `c` is a variable that will refer to an array (i.e., the variable will store an array reference). In the assignment statement, the array variable `c` receives the reference to a new array of 12 `int` elements.

### Common Programming Error 7.2

*In an array declaration, specifying the number of elements in the square brackets of the declaration (e.g., `int[12] c;`) is a syntax error.*

A program can create several arrays in a single declaration. The following declaration reserves 100 elements for `b` and 27 elements for `x`:

```
String[] b = new String[ 100 ], x = new String[ 27 ];
```

When the type of the array and the square brackets are combined at the beginning of the declaration, all the identifiers in the declaration are array variables. In this case, variables `b` and `x` refer to `String` arrays. For readability, we prefer to declare only one variable per declaration. The preceding declaration is equivalent to:

```
String[] b = new String[ 100 ]; // create array b
String[] x = new String[ 27 ]; // create array x
```

### Good Programming Practice 7.1

For readability, declare only one variable per declaration. Keep each declaration on a separate line, and include a comment describing the variable being declared.

When only one variable is declared in each declaration, the square brackets can be placed either after the type or after the array variable name, as in:

```
String b[] = new String[ 100 ]; // create array b
String x[] = new String[ 27 ]; // create array x
```

### Common Programming Error 7.3

Declaring multiple array variables in a single declaration can lead to subtle errors. Consider the declaration `int[] a, b, c;`. If `a`, `b` and `c` should be declared as array variables, then this declaration is correct—placing square brackets directly following the type indicates that all the identifiers in the declaration are array variables. However, if only `a` is intended to be an array variable, and `b` and `c` are intended to be individual `int` variables, then this declaration is incorrect—the declaration `int a[], b, c;` would achieve the desired result.

A program can declare arrays of any type. Every element of a primitive-type array contains a value of the array's declared element type. Similarly, in an array of a reference type, every element is a reference to an object of the array's declared element type. For example, every element of an `int` array is an `int` value, and every element of a `String` array is a reference to a `String` object.

## 7.4 Examples Using Arrays

This section presents several examples that demonstrate declaring arrays, creating arrays, initializing arrays and manipulating array elements.

### Creating and Initializing an Array

The application of Fig. 7.2 uses keyword `new` to create an array of 10 `int` elements, which are initially zero (the default for `int` variables). Line 8 declares `array`—a reference capable of referring to an array of `int` elements. Line 10 creates the array object and assigns its reference to variable `array`. Line 12 outputs the column headings. The first column contains the index (0–9) of each array element, and the second column contains the default value (0) of each array element.

```
1 // Fig. 7.2: InitArray.java
2 // Initializing the elements of an array to default values of zero.
3
4 public class InitArray
5 {
6     public static void main( String[] args )
7     {
8         int[] array; // declare array named array
9
10        array = new int[ 10 ]; // create the array object
```

**Fig. 7.2** | Initializing the elements of an array to default values of zero. (Part I of 2.)

```

11
12     System.out.printf( "%s%8s\n", "Index", "Value" ); // column headings
13
14     // output each array element's value
15     for ( int counter = 0; counter < array.length; counter++ )
16         System.out.printf( "%5d%8d\n", counter, array[ counter ] );
17     } // end main
18 } // end class InitArray

```

| Index | Value |
|-------|-------|
| 0     | 0     |
| 1     | 0     |
| 2     | 0     |
| 3     | 0     |
| 4     | 0     |
| 5     | 0     |
| 6     | 0     |
| 7     | 0     |
| 8     | 0     |
| 9     | 0     |

**Fig. 7.2** | Initializing the elements of an array to default values of zero. (Part 2 of 2.)

The for statement in lines 15–16 outputs the index number (represented by counter) and the value of each array element (represented by array[counter]). The loop-control variable counter is initially 0—index values start at 0, so using **zero-based counting** allows the loop to access every element of the array. The for’s loop-continuation condition uses the expression array.length (line 15) to determine the length of the array. In this example, the length of the array is 10, so the loop continues executing as long as the value of control variable counter is less than 10. The highest index value of a 10-element array is 9, so using the less-than operator in the loop-continuation condition guarantees that the loop does not attempt to access an element *beyond* the end of the array (i.e., during the final iteration of the loop, counter is 9). We’ll soon see what Java does when it encounters such an *out-of-range index* at execution time.

### Using an Array Initializer

You can create an array and initialize its elements with an **array initializer**—a comma-separated list of expressions (called an **initializer list**) enclosed in braces. In this case, the array length is determined by the number of elements in the initializer list. For example,

```
int[] n = { 10, 20, 30, 40, 50 };
```

creates a five-element array with index values 0–4. Element n[0] is initialized to 10, n[1] is initialized to 20, and so on. When the compiler encounters an array declaration that includes an initializer list, it counts the number of initializers in the list to determine the size of the array, then sets up the appropriate new operation “behind the scenes.”

The application in Fig. 7.3 initializes an integer array with 10 values (line 9) and displays the array in tabular format. The code for displaying the array elements (lines 14–15) is identical to that in Fig. 7.2 (lines 15–16).

```

1 // Fig. 7.3: InitArray.java
2 // Initializing the elements of an array with an array initializer.
3
4 public class InitArray
5 {
6     public static void main( String[] args )
7     {
8         // initializer list specifies the value for each element
9         int[] array = { 32, 27, 64, 18, 95, 14, 90, 70, 60, 37 };
10
11         System.out.printf( "%s%8s\n", "Index", "Value" ); // column headings
12
13         // output each array element's value
14         for ( int counter = 0; counter < array.length; counter++ )
15             System.out.printf( "%5d%8d\n", counter, array[ counter ] );
16     } // end main
17 } // end class InitArray

```

| Index | Value |
|-------|-------|
| 0     | 32    |
| 1     | 27    |
| 2     | 64    |
| 3     | 18    |
| 4     | 95    |
| 5     | 14    |
| 6     | 90    |
| 7     | 70    |
| 8     | 60    |
| 9     | 37    |

**Fig. 7.3** | Initializing the elements of an array with an array initializer.

### *Calculating the Values to Store in an Array*

The application in Fig. 7.4 creates a 10-element array and assigns to each element one of the even integers from 2 to 20 (2, 4, 6, ..., 20). Then the application displays the array in tabular format. The for statement at lines 12–13 calculates an array element's value by multiplying the current value of the control variable counter by 2, then adding 2.

```

1 // Fig. 7.4: InitArray.java
2 // Calculating the values to be placed into the elements of an array.
3
4 public class InitArray
5 {
6     public static void main( String[] args )
7     {
8         final int ARRAY_LENGTH = 10; // declare constant
9         int[] array = new int[ ARRAY_LENGTH ]; // create array
10
11         // calculate value for each array element
12         for ( int counter = 0; counter < array.length; counter++ )
13             array[ counter ] = 2 + 2 * counter;

```

**Fig. 7.4** | Calculating the values to be placed into the elements of an array. (Part 1 of 2.)

```

14
15     System.out.printf( "%s%8s\n", "Index", "Value" ); // column headings
16
17     // output each array element's value
18     for ( int counter = 0; counter < array.length; counter++ )
19         System.out.printf( "%5d%8d\n", counter, array[ counter ] );
20     } // end main
21 } // end class InitArray

```

| Index | Value |
|-------|-------|
| 0     | 2     |
| 1     | 4     |
| 2     | 6     |
| 3     | 8     |
| 4     | 10    |
| 5     | 12    |
| 6     | 14    |
| 7     | 16    |
| 8     | 18    |
| 9     | 20    |

**Fig. 7.4** | Calculating the values to be placed into the elements of an array. (Part 2 of 2.)

Line 8 uses the modifier `final` to declare the constant variable `ARRAY_LENGTH` with the value 10. Constant variables must be initialized before they're used and cannot be modified thereafter. If you attempt to *modify* a `final` variable after it's initialized in its declaration, the compiler issues an error message like

```
cannot assign a value to final variable variableName
```

If an attempt is made to access the value of a `final` variable before it's initialized, the compiler issues an error message like

```
variable variableName might not have been initialized
```

### Good Programming Practice 7.2

Constant variables also are called *named constants*. They often make programs more readable than programs that use literal values (e.g., 10)—a named constant such as `ARRAY_LENGTH` clearly indicates its purpose, whereas a literal value could have different meanings based on its context.

### Common Programming Error 7.4

Assigning a value to a constant variable after it has been initialized is a compilation error.

### Common Programming Error 7.5

Attempting to use a constant before it's initialized is a compilation error.

## Summing the Elements of an Array

Often, the elements of an array represent a series of values to be used in a calculation. If, for example, they represent exam grades, a professor may wish to total the elements of the

array and use that sum to calculate the class average for the exam. The GradeBook examples in Figs. 7.14 and 7.18 use this technique.

Figure 7.5 sums the values contained in a 10-element integer array. The program declares, creates and initializes the array at line 8. The for statement performs the calculations. [Note: The values supplied as array initializers are often read into a program rather than specified in an initializer list. For example, an application could input the values from a user or from a file on disk (as discussed in Chapter 17, Files, Streams and Object Serialization). Reading the data into a program (rather than “hand coding” it into the program) makes the program more reusable, because it can be used with different sets of data.]

```

1 // Fig. 7.5: SumArray.java
2 // Computing the sum of the elements of an array.
3
4 public class SumArray
5 {
6     public static void main( String[] args )
7     {
8         int[] array = { 87, 68, 94, 100, 83, 78, 85, 91, 76, 87 };
9         int total = 0;
10
11         // add each element's value to total
12         for ( int counter = 0; counter < array.length; counter++ )
13             total += array[ counter ];
14
15         System.out.printf( "Total of array elements: %d\n", total );
16     } // end main
17 } // end class SumArray

```

```
Total of array elements: 849
```

**Fig. 7.5** | Computing the sum of the elements of an array.

### *Using Bar Charts to Display Array Data Graphically*

Many programs present data to users in a graphical manner. For example, numeric values are often displayed as bars in a bar chart. In such a chart, longer bars represent proportionally larger numeric values. One simple way to display numeric data graphically is with a bar chart that shows each numeric value as a bar of asterisks (\*).

Professors often like to examine the distribution of grades on an exam. A professor might graph the number of grades in each of several categories to visualize the grade distribution. Suppose the grades on an exam were 87, 68, 94, 100, 83, 78, 85, 91, 76 and 87. They include one grade of 100, two grades in the 90s, four grades in the 80s, two grades in the 70s, one grade in the 60s and no grades below 60. Our next application (Fig. 7.6) stores this grade distribution data in an array of 11 elements, each corresponding to a category of grades. For example, array[0] indicates the number of grades in the range 0–9, array[7] the number of grades in the range 70–79 and array[10] the number of 100 grades. The GradeBook classes later in the chapter (Figs. 7.14 and 7.18) contain code that calculates these grade frequencies based on a set of grades. For now, we manually create the array with the given grade frequencies.

```

1 // Fig. 7.6: BarChart.java
2 // Bar chart printing program.
3
4 public class BarChart
5 {
6     public static void main( String[] args )
7     {
8         int[] array = { 0, 0, 0, 0, 0, 0, 0, 1, 2, 4, 2, 1 };
9
10        System.out.println( "Grade distribution:" );
11
12        // for each array element, output a bar of the chart
13        for ( int counter = 0; counter < array.length; counter++ )
14        {
15            // output bar label ( "00-09: ", ..., "90-99: ", "100: " )
16            if ( counter == 10 )
17                System.out.printf( "%5d: ", 100 );
18            else
19                System.out.printf( "%02d-%02d: ",
20                                counter * 10, counter * 10 + 9 );
21
22            // print bar of asterisks
23            for ( int stars = 0; stars < array[ counter ]; stars++ )
24                System.out.print( "*" );
25
26            System.out.println(); // start a new line of output
27        } // end outer for
28    } // end main
29 } // end class BarChart

```

```

```

**Fig. 7.6** | Bar chart printing program.

The application reads the numbers from the array and graphs the information as a bar chart. It displays each grade range followed by a bar of asterisks indicating the number of grades in that range. To label each bar, lines 16–20 output a grade range (e.g., "70-79: ") based on the current value of `counter`. When `counter` is 10, line 17 outputs 100 with a field width of 5, followed by a colon and a space, to align the label "100: " with the other bar labels. The nested `for` statement (lines 23–24) outputs the bars. Note the loop-continuation condition at line 23 (`stars < array[counter]`). Each time the program reaches the inner `for`, the loop counts from 0 up to `array[counter]`, thus using a value in `array`

to determine the number of asterisks to display. In this example, no students received a grade below 60, so `array[0]–array[5]` contain zeroes, and no asterisks are displayed next to the first six grade ranges. In line 19, the format specifier `%02d` indicates that an `int` value should be formatted as a field of two digits. The **0 flag** in the format specifier displays a leading 0 for values with fewer digits than the field width (2).

### Using the Elements of an Array as Counters

Sometimes, programs use counter variables to summarize data, such as the results of a survey. In Fig. 6.7, we used separate counters in our die-rolling program to track the number of occurrences of each side of a six-sided die as the program rolled the die 6,000,000 times. An array version of this application is shown in Fig. 7.7.

```

1 // Fig. 7.7: RollDie.java
2 // Die-rolling program using arrays instead of switch.
3 import java.util.Random;
4
5 public class RollDie
6 {
7     public static void main( String[] args )
8     {
9         Random randomNumbers = new Random(); // random number generator
10        int[] frequency = new int[ 7 ]; // array of frequency counters
11
12        // roll die 6,000,000 times; use die value as frequency index
13        for ( int roll = 1; roll <= 6000000; roll++ )
14            ++frequency[ 1 + randomNumbers.nextInt( 6 ) ];
15
16        System.out.printf( "%s%10s\n", "Face", "Frequency" );
17
18        // output each array element's value
19        for ( int face = 1; face < frequency.length; face++ )
20            System.out.printf( "%4d%10d\n", face, frequency[ face ] );
21    } // end main
22 } // end class RollDie

```

| Face | Frequency |
|------|-----------|
| 1    | 999690    |
| 2    | 999512    |
| 3    | 1000575   |
| 4    | 999815    |
| 5    | 999781    |
| 6    | 1000627   |

**Fig. 7.7** | Die-rolling program using arrays instead of `switch`.

Figure 7.7 uses the array `frequency` (line 10) to count the occurrences of each side of the die. *The single statement in line 14 of this program replaces lines 23–46 of Fig. 6.7.* Line 14 uses the random value to determine which frequency element to increment during each iteration of the loop. The calculation in line 14 produces random numbers from 1 to 6, so the array `frequency` must be large enough to store six counters. However, we use a seven-element array in which we ignore `frequency[0]`—it’s more logical to have the face value 1 increment `frequency[1]` than `frequency[0]`. Thus, each face value is used as an

index for array frequency. In line 14, the calculation inside the square brackets evaluates first to determine which element of the array to increment, then the ++ operator adds one to that element. We also replaced lines 50–52 from Fig. 6.7 by looping through array frequency to output the results (lines 19–20).

### Using Arrays to Analyze Survey Results

Our next example uses arrays to summarize data collected in a survey. Consider the following problem statement:

*Twenty students were asked to rate on a scale of 1 to 5 the quality of the food in the student cafeteria, with 1 being “awful” and 5 being “excellent.” Place the 20 responses in an integer array and determine the frequency of each rating.*

This is a typical array-processing application (Fig. 7.8). We wish to summarize the number of responses of each type (that is, 1–5). Array responses (lines 9–10) is a 20-element integer array containing the students’ survey responses. The last value in the array is intentionally an incorrect response (14). When a Java program executes, array element indices are checked for validity—all indices must be greater than or equal to 0 and less than the length of the array. Any attempt to access an element outside that range of indices results in a runtime error that’s known as an `ArrayIndexOutOfBoundsException`. At the end of this section, we’ll discuss the invalid response value, demonstrate array **bounds checking** and introduce Java’s exception-handling mechanism, which can be used to detect and handle an `ArrayIndexOutOfBoundsException`.

---

```

1 // Fig. 7.8: StudentPoll.java
2 // Poll analysis program.
3
4 public class StudentPoll
5 {
6     public static void main( String[] args )
7     {
8         // student response array (more typically, input at runtime)
9         int[] responses = { 1, 2, 5, 4, 3, 5, 2, 1, 3, 3, 1, 4, 3, 3, 3,
10            2, 3, 3, 2, 14 };
11         int[] frequency = new int[ 6 ]; // array of frequency counters
12
13         // for each answer, select responses element and use that value
14         // as frequency index to determine element to increment
15         for ( int answer = 0; answer < responses.length; answer++ )
16         {
17             try
18             {
19                 ++frequency[ responses[ answer ] ];
20             } // end try
21             catch ( ArrayIndexOutOfBoundsException e )
22             {
23                 System.out.println( e );
24                 System.out.printf( "    responses[%d] = %d\n\n",
25                    answer, responses[ answer ] );
26             } // end catch
27         } // end for

```

**Fig. 7.8** | Poll analysis program. (Part 2 of 2.)

### *The frequency Array*

We use the *six-element* array `frequency` (line 11) to count the number of occurrences of each response. Each element is used as a counter for one of the possible types of survey responses—`frequency[1]` counts the number of students who rated the food as 1, `frequency[2]` counts the number of students who rated the food as 2, and so on.

### *Summarizing the Results*

The `for` statement (lines 15–27) reads the responses from the array `responses` one at a time and increments one of the counters `frequency[1]` to `frequency[5]`; we ignore `frequency[0]` because the survey responses are limited to the range 1–5. The key statement in the loop appears in line 19. This statement increments the appropriate frequency counter as determined by the value of `responses[answer]`.

Let's step through the first few iterations of the `for` statement:

- When the counter `answer` is 0, `responses[answer]` is the value of `responses[0]` (that is, 1—see line 9). In this case, `frequency[responses[answer]]` is interpreted as `frequency[1]`, and the counter `frequency[1]` is incremented by one. To evaluate the expression, we begin with the value in the *innermost* set of brackets (`answer`, currently 0). The value of `answer` is plugged into the expression, and the next set of brackets (`responses[answer]`) is evaluated. That value is used as the index for the frequency array to determine which counter to increment (in this case, `frequency[1]`).
- The next time through the loop `answer` is 1, `responses[answer]` is the value of `responses[1]` (that is, 2—see line 9), so `frequency[responses[answer]]` is interpreted as `frequency[2]`, causing `frequency[2]` to be incremented.
- When `answer` is 2, `responses[answer]` is the value of `responses[2]` (that is, 5—see line 9), so `frequency[responses[answer]]` is interpreted as `frequency[5]`, causing `frequency[5]` to be incremented, and so on.

Regardless of the number of responses processed in the survey, only a six-element array (in which we ignore element zero) is required to summarize the results, because all the correct response values are between 1 and 5, and the index values for a six-element array are 0–5. In the program’s output, the Frequency column summarizes only 19 of the 20 values in the responses array—the last element of the array responses contains an incorrect response that was not counted.

### *Exception Handling: Processing the Incorrect Response*

An **exception** indicates a problem that occurs while a program executes. The name “exception” suggests that the problem occurs infrequently—if the “rule” is that a statement normally executes correctly, then the problem represents the “exception to the rule.” **Exception handling** enables you to create **fault-tolerant programs** that can resolve (or handle) exceptions. In many cases, this allows a program to continue executing as if no problems were encountered. For example, the StudentPoll application still displays results (Fig. 7.8), even though one of the responses was out of range. More severe problems might prevent a program from continuing normal execution, instead requiring the program to notify the user of the problem, then terminate. When the JVM or a method detects a problem, such as an invalid array index or an invalid method argument, it **throws** an exception—that is, an exception occurs.

### *The try Statement*

To handle an exception, place any code that might throw an exception in a **try statement** (lines 17–26). The **try block** (lines 17–20) contains the code that might *throw* an exception, and the **catch block** (lines 21–26) contains the code that *handles* the exception if one occurs. You can have many catch blocks to handle different types of exceptions that might be thrown in the corresponding try block. When line 19 correctly increments an element of the frequency array, lines 21–26 are ignored. The braces that delimit the bodies of the try and catch blocks are required.

### *Executing the catch Block*

When the program encounters the value 14 in the responses array, it attempts to add 1 to frequency[14], which is *outside* the bounds of the array—the frequency array has only six elements. Because array bounds checking is performed at execution time, the JVM generates an exception—specifically line 19 throws an **ArrayIndexOutOfBoundsException** to notify the program of this problem. At this point the try block terminates and the catch block begins executing—if you declared any variables in the try block, they’re now out of scope and are not accessible in the catch block.

The catch block declares a type (IndexOutOfRangeException) and an exception parameter (e). The catch block can handle exceptions of the specified type. Inside the catch block, you can use the parameter’s identifier to interact with a caught exception object.

#### **Error-Prevention Tip 7.1**

*When writing code to access an array element, ensure that the array index remains greater than or equal to 0 and less than the length of the array. This helps prevent ArrayIndexOutOfBoundsException in your program.*

**toString Method of the Exception Parameter**

When lines 21–26 *catch* the exception, the program displays a message indicating the problem that occurred. Line 23 implicitly calls the exception object's `toString` method to get the error message that is stored in the exception object and display it. Once the message is displayed in this example, the exception is considered handled and the program continues with the next statement after the `catch` block's closing brace. In this example, the end of the `for` statement is reached (line 27), so the program continues with the increment of the control variable in line 15. We use exception handling again in Chapter 8, and Chapter 11 presents a deeper look at exception handling.

## 7.5 Case Study: Card Shuffling and Dealing Simulation

The examples in the chapter thus far have used arrays containing elements of primitive types. Recall from Section 7.2 that the elements of an array can be either primitive types or reference types. This section uses random-number generation and an array of reference-type elements, namely objects representing playing cards, to develop a class that simulates card shuffling and dealing. This class can then be used to implement applications that play specific card games. The exercises at the end of the chapter use the classes developed here to build a simple poker application.

We first develop class `Card` (Fig. 7.9), which represents a playing card that has a face (e.g., "Ace", "Deuce", "Three", ..., "Jack", "Queen", "King") and a suit (e.g., "Hearts", "Diamonds", "Clubs", "Spades"). Next, we develop the `DeckOfCards` class (Fig. 7.10), which creates a deck of 52 playing cards in which each element is a `Card` object. We then build a test application (Fig. 7.11) that demonstrates class `DeckOfCards`'s card shuffling and dealing capabilities.

**Class Card**

Class `Card` (Fig. 7.9) contains two `String` instance variables—`face` and `suit`—that are used to store references to the face name and suit name for a specific `Card`. The constructor for the class (lines 10–14) receives two `Strings` that it uses to initialize `face` and `suit`. Method `toString` (lines 17–20) creates a `String` consisting of the face of the card, the `String` " of " and the suit of the card. `Card`'s `toString` method can be invoked explicitly to obtain a string representation of a `Card` object (e.g., "Ace of Spades"). The `toString` method of an object is called *implicitly* when the object is used where a `String` is expected (e.g., when `printf` outputs the object as a `String` using the `%s` format specifier or when the object is concatenated to a `String` using the `+` operator). For this behavior to occur, `toString` must be declared with the header shown in Fig. 7.9.

---

```

1 // Fig. 7.9: Card.java
2 // Card class represents a playing card.
3
4 public class Card
5 {
6     private String face; // face of card ("Ace", "Deuce", ...)
7     private String suit; // suit of card ("Hearts", "Diamonds", ...)
8

```

---

**Fig. 7.9** | Card class represents a playing card. (Part I of 2.)

```

9 // two-argument constructor initializes card's face and suit
10 public Card( String cardFace, String cardSuit )
11 {
12     face = cardFace; // initialize face of card
13     suit = cardSuit; // initialize suit of card
14 } // end two-argument Card constructor
15
16 // return String representation of Card
17 public String toString()
18 {
19     return face + " of " + suit;
20 } // end method toString
21 } // end class Card

```

**Fig. 7.9** | Card class represents a playing card. (Part 2 of 2.)

### *Class DeckOfCards*

Class `DeckOfCards` (Fig. 7.10) declares as an instance variable a `Card` array named `deck` (line 7). An array of a reference type is declared like any other array. Class `DeckOfCards` also declares an integer instance variable `currentCard` (line 8) representing the next `Card` to be dealt from the `deck` array and a named constant `NUMBER_OF_CARDS` (line 9) indicating the number of `Cards` in the deck (52).

```

1 // Fig. 7.10: DeckOfCards.java
2 // DeckOfCards class represents a deck of playing cards.
3 import java.util.Random;
4
5 public class DeckOfCards
6 {
7     private Card[] deck; // array of Card objects
8     private int currentCard; // index of next Card to be dealt (0-51)
9     private static final int NUMBER_OF_CARDS = 52; // constant # of Cards
10    // random number generator
11    private static final Random randomNumbers = new Random();
12
13    // constructor fills deck of Cards
14    public DeckOfCards()
15    {
16        String[] faces = { "Ace", "Deuce", "Three", "Four", "Five", "Six",
17                          "Seven", "Eight", "Nine", "Ten", "Jack", "Queen", "King" };
18        String[] suits = { "Hearts", "Diamonds", "Clubs", "Spades" };
19
20        deck = new Card[ NUMBER_OF_CARDS ]; // create array of Card objects
21        currentCard = 0; // set currentCard so first Card dealt is deck[ 0 ]
22
23        // populate deck with Card objects
24        for ( int count = 0; count < deck.length; count++ )
25        {
26            deck[ count ] =
27                new Card( faces[ count % 13 ], suits[ count / 13 ] );
28        } // end DeckOfCards constructor

```

**Fig. 7.10** | `DeckOfCards` class represents a deck of playing cards. (Part 1 of 2.)

```

29 // shuffle deck of Cards with one-pass algorithm
30 public void shuffle()
31 {
32     // after shuffling, dealing should start at deck[ 0 ] again
33     currentCard = 0; // reinitialize currentCard
34
35     // for each Card, pick another random Card (0-51) and swap them
36     for ( int first = 0; first < deck.length; first++ )
37     {
38         // select a random number between 0 and 51
39         int second = randomNumbers.nextInt( NUMBER_OF_CARDS );
40
41         // swap current Card with randomly selected Card
42         Card temp = deck[ first ];
43         deck[ first ] = deck[ second ];
44         deck[ second ] = temp;
45     } // end for
46 } // end method shuffle
47
48 // deal one Card
49 public Card dealCard()
50 {
51     // determine whether Cards remain to be dealt
52     if ( currentCard < deck.length )
53         return deck[ currentCard++ ]; // return current Card in array
54     else
55         return null; // return null to indicate that all Cards were dealt
56 } // end method dealCard
57 } // end class DeckOfCards

```

**Fig. 7.10** | DeckOfCards class represents a deck of playing cards. (Part 2 of 2.)

### *DeckOfCards Constructor*

The class's constructor instantiates the deck array (line 20) with NUMBER\_OF\_CARDS (52) elements. The elements of deck are null by default, so the constructor uses a for statement (lines 24–26) to fill the deck with Cards. The loop initializes control variable count to 0 and loops while count is less than deck.length, causing count to take on each integer value from 0 to 51 (the indices of the deck array). Each Card is instantiated and initialized with two Strings—one from the faces array (which contains the Strings "Ace" through "King") and one from the suits array (which contains the Strings "Hearts", "Diamonds", "Clubs" and "Spades"). The calculation count % 13 always results in a value from 0 to 12 (the 13 indices of the faces array in lines 16–17), and the calculation count / 13 always results in a value from 0 to 3 (the four indices of the suits array in line 18). When the deck array is initialized, it contains the Cards with faces "Ace" through "King" in order for each suit ("Hearts" then "Diamonds" then "Clubs" then "Spades"). We use arrays of Strings to represent the faces and suits in this example. In Exercise 7.34, we ask you to modify this example to use arrays of enumeration constants to represent the faces and suits.

### *DeckOfCards Method shuffle*

Method shuffle (lines 30–46) shuffles the Cards in the deck. The method loops through all 52 Cards (array indices 0 to 51). For each Card, a number between 0 and 51 is picked

randomly to select another Card. Next, the current Card object and the randomly selected Card object are swapped in the array. This exchange is performed by the three assignments in lines 42–44. The extra variable `temp` temporarily stores one of the two Card objects being swapped. The swap cannot be performed with only the two statements

```
deck[ first ] = deck[ second ];
deck[ second ] = deck[ first ];
```

If `deck[first]` is the "Ace" of "Spades" and `deck[second]` is the "Queen" of "Hearts", after the first assignment, both array elements contain the "Queen" of "Hearts" and the "Ace" of "Spades" is lost—hence, the extra variable `temp` is needed. After the for loop terminates, the Card objects are randomly ordered. A total of only 52 swaps are made in a single pass of the entire array, and the array of Card objects is shuffled!

[*Note:* It's recommended that you use a so-called unbiased shuffling algorithm for real card games. Such an algorithm ensures that all possible shuffled card sequences are equally likely to occur. A popular unbiased shuffling algorithm is the Fisher-Yates algorithm.]

### *DeckOfCards Method dealCard*

Method `dealCard` (lines 49–56) deals one Card in the array. Recall that `currentCard` indicates the index of the next Card to be dealt (i.e., the Card at the top of the deck). Thus, line 52 compares `currentCard` to the length of the deck array. If the deck is not empty (i.e., `currentCard` is less than 52), line 53 returns the “top” Card and postincrements `currentCard` to prepare for the next call to `dealCard`—otherwise, `null` is returned. Recall from Chapter 3 that `null` represents a “reference to nothing.”

### *Shuffling and Dealing Cards*

Figure 7.11 demonstrates class `DeckOfCards` (Fig. 7.10). Line 9 creates a `DeckOfCards` object named `myDeckOfCards`. The `DeckOfCards` constructor creates the deck with the 52 Card objects in order by suit and face. Line 10 invokes `myDeckOfCards`'s `shuffle` method to rearrange the Card objects. Lines 13–20 deal all 52 Cards and print them in four columns of 13 Cards each. Line 16 deals one Card object by invoking `myDeckOfCards`'s `dealCard` method, then displays the Card left justified in a field of 19 characters. When a Card is output as a String, the Card's `toString` method (lines 17–20 of Fig. 7.9) is implicitly invoked. Lines 18–19 start a new line after every four Cards.

---

```
1 // Fig. 7.11: DeckOfCardsTest.java
2 // Card shuffling and dealing.
3
4 public class DeckOfCardsTest
5 {
6     // execute application
7     public static void main( String[] args )
8     {
9         DeckOfCards myDeckOfCards = new DeckOfCards();
10        myDeckOfCards.shuffle(); // place Cards in random order
11    }
```

---

**Fig. 7.11** | Card shuffling and dealing. (Part 1 of 2.)

```

12     // print all 52 Cards in the order in which they are dealt
13     for ( int i = 1; i <= 52; i++ )
14     {
15         // deal and display a Card
16         System.out.printf( "%-19s", myDeckOfCards.dealCard() );
17
18         if ( i % 4 == 0 ) // output a newline after every fourth card
19             System.out.println();
20     } // end for
21 } // end main
22 } // end class DeckOfCardsTest

```

|                   |                   |                   |                  |
|-------------------|-------------------|-------------------|------------------|
| Six of Spades     | Eight of Spades   | Six of Clubs      | Nine of Hearts   |
| Queen of Hearts   | Seven of Clubs    | Nine of Spades    | King of Hearts   |
| Three of Diamonds | Deuce of Clubs    | Ace of Hearts     | Ten of Spades    |

| Deuce of Spades   | Eight of Hearts   | Five of Hearts    | Queen of Spades  |
| Jack of Hearts    | Seven of Spades   | Four of Clubs     | Nine of Diamonds |
| Ace of Diamonds   | Queen of Diamonds | Five of Clubs     | King of Spades   |
| Five of Diamonds  | Ten of Clubs      | Jack of Spades    | Jack of Clubs    |

**Fig. 7.11** | Card shuffling and dealing. (Part 2 of 2.)

## 7.6 Enhanced for Statement

The **enhanced for statement** iterates through the elements of an array *without* using a counter, thus avoiding the possibility of “stepping outside” the array. We show how to use the enhanced for statement with the Java API’s prebuilt data structures (called collections) in Section 7.14. The syntax of an enhanced for statement is:

```

for ( parameter : arrayName )
    statement

```

where *parameter* has a type and an identifier (e.g., `int number`), and *arrayName* is the array through which to iterate. The type of the parameter must be consistent with the type of the elements in the array. As the next example illustrates, the identifier represents successive element values in the array on successive iterations of the loop.

Figure 7.12 uses the enhanced for statement (lines 12–13) to sum the integers in an array of student grades. The enhanced for’s parameter is of type `int`, because array contains `int` values—the loop selects one `int` value from the array during each iteration. The enhanced for statement iterates through successive values in the array one by one. The statement’s header can be read as “for each iteration, assign the next element of array to `int` variable `number`, then execute the following statement.” Thus, for each iteration, identifier `number` represents an `int` value in array. Lines 12–13 are equivalent to the following counter-controlled repetition used in lines 12–13 of Fig. 7.5 to total the integers in array, except that counter cannot be accessed in the enhanced for statement:

```

for ( int counter = 0; counter < array.length; counter++ )
    total += array[ counter ];

```

```

1 // Fig. 7.12: EnhancedForTest.java
2 // Using the enhanced for statement to total integers in an array.
3
4 public class EnhancedForTest
5 {
6     public static void main( String[] args )
7     {
8         int[] array = { 87, 68, 94, 100, 83, 78, 85, 91, 76, 87 };
9         int total = 0;
10
11         // add each element's value to total
12         for ( int number : array )
13             total += number;
14
15         System.out.printf( "Total of array elements: %d\n", total );
16     } // end main
17 } // end class EnhancedForTest

```

```
Total of array elements: 849
```

**Fig. 7.12** | Using the enhanced for statement to total integers in an array.

The enhanced for statement simplifies the code for iterating through an array. Note, however, that *the enhanced for statement can be used only to obtain array elements—it cannot be used to modify elements*. If your program needs to modify elements, use the traditional counter-controlled for statement.

The enhanced for statement can be used in place of the counter-controlled for statement whenever code looping through an array does *not* require access to the counter indicating the index of the current array element. For example, totaling the integers in an array requires access only to the element values—the index of each element is irrelevant. However, if a program must use a counter for some reason other than simply to loop through an array (e.g., to print an index number next to each array element value, as in the examples earlier in this chapter), use the counter-controlled for statement.

## 7.7 Passing Arrays to Methods

This section demonstrates how to pass arrays and individual array elements as arguments to methods. To pass an array argument to a method, specify the name of the array without any brackets. For example, if array `hourlyTemperatures` is declared as

```
double[] hourlyTemperatures = new double[ 24 ];
```

then the method call

```
modifyArray( hourlyTemperatures );
```

passes the reference of array `hourlyTemperatures` to method `modifyArray`. Every array object “knows” its own length (via its `length` field). Thus, when we pass an array object’s reference into a method, we need not pass the array length as an additional argument.

For a method to receive an array reference through a method call, the method’s parameter list must specify an array parameter. For example, the method header for method `modifyArray` might be written as

```
void modifyArray( double[] b )
```

indicating that `modifyArray` receives the reference of a `double` array in parameter `b`. The method call passes array `hourlyTemperature`'s reference, so when the called method uses the array variable `b`, it *refers to* the same array object as `hourlyTemperatures` in the caller.

When an argument to a method is an entire array or an individual array element of a reference type, the called method receives a *copy* of the reference. However, when an argument to a method is an individual array element of a primitive type, the called method receives a copy of the element's *value*. Such primitive values are called **scalars** or **scalar quantities**. To pass an individual array element to a method, use the indexed name of the array element as an argument in the method call.

Figure 7.13 demonstrates the difference between passing an entire array and passing a primitive-type array element to a method. Notice that `main` invokes static methods `modifyArray` (line 19) and `modifyElement` (line 30) directly. Recall from Section 6.4 that a static method of a class can invoke other static methods of the same class directly.

---

```

1 // Fig. 7.13: PassArray.java
2 // Passing arrays and individual array elements to methods.
3
4 public class PassArray
5 {
6     // main creates array and calls modifyArray and modifyElement
7     public static void main( String[] args )
8     {
9         int[] array = { 1, 2, 3, 4, 5 };
10
11         System.out.println(
12             "Effects of passing reference to entire array:\n" +
13             "The values of the original array are:" );
14
15         // output original array elements
16         for ( int value : array )
17             System.out.printf( " %d", value );
18
19         modifyArray( array ); // pass array reference
20         System.out.println( "\n\nThe values of the modified array are:" );
21
22         // output modified array elements
23         for ( int value : array )
24             System.out.printf( " %d", value );
25
26         System.out.printf(
27             "\n\nEffects of passing array element value:\n" +
28             "array[3] before modifyElement: %d\n", array[ 3 ] );
29
30         modifyElement( array[ 3 ] ); // attempt to modify array[ 3 ]
31         System.out.printf(
32             "array[3] after modifyElement: %d\n", array[ 3 ] );
33     } // end main
34

```

**Fig. 7.13** | Passing arrays and individual array elements to methods. (Part 1 of 2.)

```

35 // multiply each element of an array by 2
36 public static void modifyArray( int[] array2 )
37 {
38     for ( int counter = 0; counter < array2.length; counter++ )
39         array2[ counter ] *= 2;
40 } // end method modifyArray
41
42 // multiply argument by 2
43 public static void modifyElement( int element )
44 {
45     element *= 2;
46     System.out.printf(
47         "Value of element in modifyElement: %d\n", element );
48 } // end method modifyElement
49 } // end class PassArray

```

Effects of passing reference to entire array:

The values of the original array are:

1 2 3 4 5

The values of the modified array are:

2 4 6 8 10

Effects of passing array element value:

array[3] before modifyElement: 8

Value of element in modifyElement: 16

array[3] after modifyElement: 8

**Fig. 7.13** | Passing arrays and individual array elements to methods. (Part 2 of 2.)

The enhanced for statement at lines 16–17 outputs the five `int` elements of array. Line 19 invokes method `modifyArray`, passing array as an argument. Method `modifyArray` (lines 36–40) receives a copy of array’s reference and uses the reference to multiply each of array’s elements by 2. To prove that array’s elements were modified, lines 23–24 output the five elements of array again. As the output shows, method `modifyArray` doubled the value of each element. We could not use the enhanced for statement in lines 38–39 because we’re modifying the array’s elements.

Figure 7.13 next demonstrates that when a copy of an individual primitive-type array element is passed to a method, modifying the *copy* in the called method does *not* affect the original value of that element in the calling method’s array. Lines 26–28 output the value of `array[3]` *before* invoking method `modifyElement`. Remember that the value of this element is now 8 after it was modified in the call to `modifyArray`. Line 30 calls method `modifyElement` and passes `array[3]` as an argument. Remember that `array[3]` is actually one `int` value (8) in array. Therefore, the program passes a copy of the value of `array[3]`. Method `modifyElement` (lines 43–48) multiplies the value received as an argument by 2, stores the result in its parameter `element`, then outputs the value of `element` (16). Since method parameters, like local variables, cease to exist when the method in which they’re declared completes execution, the method parameter `element` is destroyed when method `modifyElement` terminates. When the program returns control to `main`, lines 31–32 output the *unmodified* value of `array[3]` (i.e., 8).

*Notes on Passing Arguments to Methods*

The preceding example demonstrated how arrays and primitive-type array elements are passed as arguments to methods. We now take a closer look at how arguments in general are passed to methods. Two ways to pass arguments in method calls in many programming languages are **pass-by-value** and **pass-by-reference** (also called **call-by-value** and **call-by-reference**). When an argument is passed by value, a copy of the argument's *value* is passed to the called method. The called method works exclusively with the copy. Changes to the called method's copy do *not* affect the original variable's value in the caller.

When an argument is passed by reference, the called method can access the argument's value in the caller directly and modify that data, if necessary. Pass-by-reference improves performance by eliminating the need to copy possibly large amounts of data.

Unlike some other languages, Java does *not* allow you to choose pass-by-value or pass-by-reference—*all arguments are passed by value*. A method call can pass two types of values to a method—copies of primitive values (e.g., values of type `int` and `double`) and copies of references to objects. Objects themselves cannot be passed to methods. When a method modifies a primitive-type parameter, changes to the parameter have no effect on the original argument value in the calling method. For example, when line 30 in `main` of Fig. 7.13 passes `array[3]` to method `modifyElement`, the statement in line 45 that doubles the value of parameter `element` has *no* effect on the value of `array[3]` in `main`. This is also true for reference-type parameters. If you modify a reference-type parameter so that it refers to another object, only the parameter refers to the new object—the reference stored in the caller's variable still refers to the original object.

Although an object's reference is passed by value, a method can still interact with the referenced object by calling its `public` methods using the copy of the object's reference. Since the reference stored in the parameter is a copy of the reference that was passed as an argument, the parameter in the called method and the argument in the calling method refer to the same object in memory. For example, in Fig. 7.13, both parameter `array2` in method `modifyArray` and variable `array` in `main` refer to the *same* array object in memory. Any changes made using the parameter `array2` are carried out on the object that `array` references in the calling method. In Fig. 7.13, the changes made in `modifyArray` using `array2` affect the contents of the array object referenced by `array` in `main`. Thus, with a reference to an object, the called method *can* manipulate the caller's object directly.

**Performance Tip 7.1**

*Passing arrays by reference makes sense for performance reasons. If arrays were passed by value, a copy of each element would be passed. For large, frequently passed arrays, this would waste time and consume considerable storage for the copies of the arrays.*

## 7.8 Case Study: Class `GradeBook` Using an Array to Store Grades

Previous versions of class `GradeBook` process a set of grades entered by the user, but do not maintain the individual grade values in instance variables of the class. Thus, repeat calculations require the user to reenter the same grades. One way to solve this problem would be to store each grade entered in an individual instance of the class. For example, we could create instance variables `grade1`, `grade2`, ..., `grade10` in class `GradeBook` to store 10 stu-

dent grades. But this would make the code to total the grades and determine the class average cumbersome, and the class would not be able to process any more than 10 grades at a time. We solve this problem by storing grades in an array.

### Storing Student Grades in an Array in Class GradeBook

Class GradeBook (Fig. 7.14) uses an array of ints to store several students' grades on a single exam. This eliminates the need to repeatedly input the same set of grades. Array grades is declared as an instance variable (line 7), so each GradeBook object maintains its own set of grades. The constructor (lines 10–14) has two parameters—the name of the course and an array of grades. When an application (e.g., class GradeBookTest in Fig. 7.15) creates a GradeBook object, the application passes an existing int array to the constructor, which assigns the array's reference to instance variable grades (line 13). The grades array's size is determined by the length of the array that's passed to the constructor. Thus, a GradeBook object can process a variable number of grades. The grade values in the passed array could have been input from a user or read from a file on disk (as discussed in Chapter 17). In our test application, we initialize an array with grade values (Fig. 7.15, line 10). Once the grades are stored in instance variable grades of class GradeBook, all the class's methods can access the elements of grades *as often as needed* to perform various calculations.

Method processGrades (lines 37–51) contains a series of method calls that output a report summarizing the grades. Line 40 calls method outputGrades to print the contents of the array grades. Lines 134–136 in method outputGrades use a for statement to output the students' grades. A counter-controlled for *must* be used in this case, because lines 135–136 use counter variable student's value to output each grade next to a particular student number (see output in Fig. 7.15). Although array indices start at 0, a professor would typically number students starting at 1. Thus, lines 135–136 output student + 1 as the student number to produce grade labels "Student 1: ", "Student 2: ", and so on.

94     // return average of grades
95     return (double) total / grades.length;
96 } // end method getAverage
97
98 // output bar chart displaying grade distribution
99 public void outputBarChart()
100 {
101     System.out.println( "Grade distribution:" );
102
103     // stores frequency of grades in each range of 10 grades
104     int[] frequency = new int[ 11 ];
105
106     // for each grade, increment the appropriate frequency
107     for ( int grade : grades )
108         ++frequency[ grade / 10 ];
109
110     // for each grade frequency, print bar in chart
111     for ( int count = 0; count < frequency.length; count++ )
112     {
113         // output bar label ( "00-09: ", ..., "90-99: ", "100: " )
114         if ( count == 10 )
115             System.out.printf( "%5d: ", 100 );
116         else
117             System.out.printf( "%02d-%02d: ",
118                 count * 10, count * 10 + 9 );
119
120         // print bar of asterisks
121         for ( int stars = 0; stars < frequency[ count ]; stars++ )
122             System.out.print( "*" );
123
124         System.out.println(); // start a new line of output
125     } // end outer for
126 } // end method outputBarChart
```

**Fig. 7.14** | GradeBook class using an array to store test grades. (Part 3 of 4.)

```

127
128 // output the contents of the grades array
129 public void outputGrades()
130 {
131     System.out.println( "The grades are:\n" );
132
133     // output each student's grade
134     for ( int student = 0; student < grades.length; student++ )
135         System.out.printf( "Student %2d: %3d\n",
136                             student + 1, grades[ student ] );
137 } // end method outputGrades
138 } // end class GradeBook

```

**Fig. 7.14** | GradeBook class using an array to store test grades. (Part 4 of 4.)

Method `processGrades` next calls method `getAverage` (line 43) to obtain the average of the grades in the array. Method `getAverage` (lines 86–96) uses an enhanced `for` statement to total the values in array `grades` before calculating the average. The parameter in the enhanced `for`'s header (e.g., `int grade`) indicates that for each iteration, the `int` variable `grade` takes on a value in the array `grades`. The averaging calculation in line 95 uses `grades.length` to determine the number of grades being averaged.

Lines 46–47 in method `processGrades` call methods `getMinimum` and `getMaximum` to determine the lowest and highest grades of any student on the exam, respectively. Each of these methods uses an enhanced `for` statement to loop through array `grades`. Lines 59–64 in method `getMinimum` loop through the array. Lines 62–63 compare each grade to `lowGrade`; if a grade is less than `lowGrade`, `lowGrade` is set to that grade. When line 66 executes, `lowGrade` contains the lowest grade in the array. Method `getMaximum` (lines 70–83) works similarly to method `getMinimum`.

Finally, line 50 in method `processGrades` calls method `outputBarChart` to print a distribution chart of the grade data using a technique similar to that in Fig. 7.6. In that example, we manually calculated the number of grades in each category (i.e., 0–9, 10–19, ..., 90–99 and 100) by simply looking at a set of grades. In this example, lines 107–108 use a technique similar to that in Figs. 7.7 and 7.8 to calculate the frequency of grades in each category. Line 104 declares and creates array `frequency` of 11 `ints` to store the frequency of grades in each grade category. For each grade in array `grades`, lines 107–108 increment the appropriate element of the `frequency` array. To determine which element to increment, line 108 divides the current grade by 10 using integer division. For example, if `grade` is 85, line 108 increments `frequency[8]` to update the count of grades in the range 80–89. Lines 111–125 next print the bar chart (see Fig. 7.15) based on the values in array `frequency`. Like lines 23–24 of Fig. 7.6, lines 121–122 of Fig. 7.14 use a value in array `frequency` to determine the number of asterisks to display in each bar.

### *Class GradeBookTest That Demonstrates Class GradeBook*

The application of Fig. 7.15 creates an object of class `GradeBook` (Fig. 7.14) using the `int` array `gradesArray` (declared and initialized in line 10). Lines 12–13 pass a course name and `gradesArray` to the `GradeBook` constructor. Line 14 displays a welcome message, and line 15 invokes the `GradeBook` object's `processGrades` method. The output summarizes the 10 grades in `myGradeBook`.

### Software Engineering Observation 7.1

A test harness (or test application) is responsible for creating an object of the class being tested and providing it with data. This data could come from any of several sources. Test data can be placed directly into an array with an array initializer, it can come from the user at the keyboard, it can come from a file (as you'll see in Chapter 17), or it can come from a network (as you'll see in Chapter 27). After passing this data to the class's constructor to instantiate the object, the test harness should call upon the object to test its methods and manipulate its data. Gathering data in the test harness like this allows the class to manipulate data from several sources.

```

```

**Fig. 7.15** | GradeBookTest creates a GradeBook object using an array of grades, then invokes method processGrades to analyze them. (Part 2 of 2.)

## 7.9 Multidimensional Arrays

Multidimensional arrays with two dimensions are often used to represent *tables* of values consisting of information arranged in *rows* and *columns*. To identify a particular table element, we must specify two indices. *By convention*, the first identifies the element's row and the second its column. Arrays that require two indices to identify a particular element are called **two-dimensional arrays**. (Multidimensional arrays can have more than two dimensions.) Java does not support multidimensional arrays directly, but it does allow you to specify one-dimensional arrays whose elements are also one-dimensional arrays, thus achieving the same effect. Figure 7.16 illustrates a two-dimensional array named `a` that contains three rows and four columns (i.e., a three-by-four array). In general, an array with  $m$  rows and  $n$  columns is called an  *$m$ -by- $n$  array*.

**Fig. 7.16** | Two-dimensional array with three rows and four columns.

Every element in array `a` is identified in Fig. 7.16 by an *array-access expression* of the form `a[row][column]`; `a` is the name of the array, and `row` and `column` are the indices that uniquely identify each element in array `a` by row and column number. The names of the elements in `row 0` all have a first index of 0, and the names of the elements in `column 3` all have a second index of 3.

### Arrays of One-Dimensional Arrays

Like one-dimensional arrays, multidimensional arrays can be initialized with array initializers in declarations. A two-dimensional array `b` with two rows and two columns could be declared and initialized with **nested array initializers** as follows:

```
int[][] b = { { 1, 2 }, { 3, 4 } };
```

The initial values are grouped by row in braces. So 1 and 2 initialize `b[0][0]` and `b[0][1]`, respectively, and 3 and 4 initialize `b[1][0]` and `b[1][1]`, respectively. The compiler counts the number of nested array initializers (represented by sets of braces within the outer braces) to determine the number of rows in array `b`. The compiler counts the initializer values in the nested array initializer for a row to determine the number of columns in that row. As we'll see momentarily, this means that *rows can have different lengths*.

Multidimensional arrays are maintained as arrays of one-dimensional arrays. Therefore array `b` in the preceding declaration is actually composed of two separate one-dimensional arrays—one containing the values in the first nested initializer list `{ 1, 2 }` and one containing the values in the second nested initializer list `{ 3, 4 }`. Thus, array `b` itself is an array of two elements, each a one-dimensional array of `int` values.

### Two-Dimensional Arrays with Rows of Different Lengths

The manner in which multidimensional arrays are represented makes them quite flexible. In fact, the lengths of the rows in array `b` are *not* required to be the same. For example,

```
int[][] b = { { 1, 2 }, { 3, 4, 5 } };
```

creates integer array `b` with two elements (determined by the number of nested array initializers) that represent the rows of the two-dimensional array. Each element of `b` is a reference to a one-dimensional array of `int` variables. The `int` array for row 0 is a one-dimensional array with two elements (1 and 2), and the `int` array for row 1 is a one-dimensional array with three elements (3, 4 and 5).

### Creating Two-Dimensional Arrays with Array-Creation Expressions

A multidimensional array with the same number of columns in every row can be created with an array-creation expression. For example, the following lines declare array `b` and assign it a reference to a three-by-four array:

```
int[][] b = new int[ 3 ][ 4 ];
```

In this case, we use the literal values 3 and 4 to specify the number of rows and number of columns, respectively, but this is not required. Programs can also use variables to specify array dimensions, because *new creates arrays at execution time—not at compile time*. As with one-dimensional arrays, the elements of a multidimensional array are initialized when the array object is created.

A multidimensional array in which each row has a different number of columns can be created as follows:

```
int[][] b = new int[ 2 ][ ] ; // create 2 rows
b[ 0 ] = new int[ 5 ] ; // create 5 columns for row 0
b[ 1 ] = new int[ 3 ] ; // create 3 columns for row 1
```

The preceding statements create a two-dimensional array with two rows. Row 0 has five columns, and row 1 has three columns.

*Two-Dimensional Array Example: Displaying Element Values*

Figure 7.17 demonstrates initializing two-dimensional arrays with array initializers and using nested for loops to **traverse** the arrays (i.e., manipulate every element of each array). Class `InitArray`'s `main` declares two arrays. The declaration of `array1` (line 9) uses nested array initializers of the *same* length to initialize the first row to the values 1, 2 and 3, and the second row to the values 4, 5 and 6. The declaration of `array2` (line 10) uses nested initializers of *different* lengths. In this case, the first row is initialized to two elements with the values 1 and 2, respectively. The second row is initialized to one element with the value 3. The third row is initialized to three elements with the values 4, 5 and 6, respectively.

```

1 // Fig. 7.17: InitArray.java
2 // Initializing two-dimensional arrays.
3
4 public class InitArray
5 {
6     // create and output two-dimensional arrays
7     public static void main( String[] args )
8     {
9         int[][] array1 = { { 1, 2, 3 }, { 4, 5, 6 } };
10        int[][] array2 = { { 1, 2 }, { 3 }, { 4, 5, 6 } };
11
12        System.out.println( "Values in array1 by row are" );
13        outputArray( array1 ); // displays array1 by row
14
15        System.out.println( "\nValues in array2 by row are" );
16        outputArray( array2 ); // displays array2 by row
17    } // end main
18
19    // output rows and columns of a two-dimensional array
20    public static void outputArray( int[][] array )
21    {
22        // loop through array's rows
23        for ( int row = 0; row < array.length; row++ )
24        {
25            // loop through columns of current row
26            for ( int column = 0; column < array[ row ].length; column++ )
27                System.out.printf( "%d ", array[ row ][ column ] );
28
29            System.out.println(); // start new line of output
30        } // end outer for
31    } // end method outputArray
32 } // end class InitArray

```

```

Values in array1 by row are
1 2 3
4 5 6

Values in array2 by row are
1 2
3
4 5 6

```

**Fig. 7.17** | Initializing two-dimensional arrays.

Lines 13 and 16 call method `outputArray` (lines 20–31) to output the elements of `array1` and `array2`, respectively. Method `outputArray`'s parameter—`int[][] array`—indicates that the method receives a two-dimensional array. The `for` statement (lines 23–30) outputs the rows of a two-dimensional array. In the loop-continuation condition of the outer `for` statement, the expression `array.length` determines the number of rows in the array. In the inner `for` statement, the expression `array[row].length` determines the number of columns in the current row of the array. The inner `for` statement's condition enables the loop to determine the exact number of columns in each row.

### *Common Multidimensional-Array Manipulations Performed with `for` Statements*

Many common array manipulations use `for` statements. As an example, the following `for` statement sets all the elements in row 2 of array `a` in Fig. 7.16 to zero:

```
for ( int column = 0; column < a[ 2 ].length; column++)
    a[ 2 ][ column ] = 0;
```

We specified row 2; therefore, we know that the first index is always 2 (0 is the first row, and 1 is the second row). This `for` loop varies only the second index (i.e., the column index). If row 2 of array `a` contains four elements, then the preceding `for` statement is equivalent to the assignment statements

```
a[ 2 ][ 0 ] = 0;
a[ 2 ][ 1 ] = 0;
a[ 2 ][ 2 ] = 0;
a[ 2 ][ 3 ] = 0;
```

The following nested `for` statement totals the values of all the elements in array `a`:

```
int total = 0;
for ( int row = 0; row < a.length; row++ )
{
    for ( int column = 0; column < a[ row ].length; column++ )
        total += a[ row ][ column ];
} // end outer for
```

These nested `for` statements total the array elements one row at a time. The outer `for` statement begins by setting the row index to 0 so that the first row's elements can be totaled by the inner `for` statement. The outer `for` then increments `row` to 1 so that the second row can be totaled. Then, the outer `for` increments `row` to 2 so that the third row can be totaled. The variable `total` can be displayed when the outer `for` statement terminates. In the next example, we show how to process a two-dimensional array in a similar manner using nested enhanced `for` statements.

## 7.10 Case Study: Class GradeBook Using a Two-Dimensional Array

In Section 7.8, we presented class `GradeBook` (Fig. 7.14), which used a one-dimensional array to store student grades on a single exam. In most semesters, students take several exams. Professors are likely to want to analyze grades across the entire semester, both for a single student and for the class as a whole.

*Storing Student Grades in a Two-Dimensional Array in Class GradeBook*

Figure 7.18 contains a `GradeBook` class that uses a two-dimensional array `grades` to store the grades of a number of students on multiple exams. Each row of the array represents a single student's grades for the entire course, and each column represents the grades of all the students who took a particular exam. Class `GradeBookTest` (Fig. 7.19) passes the array as an argument to the `GradeBook` constructor. In this example, we use a ten-by-three array for ten students' grades on three exams. Five methods perform array manipulations to process the grades. Each method is similar to its counterpart in the earlier one-dimensional array version of `GradeBook` (Fig. 7.14). Method `getMinimum` (lines 52–70) determines the lowest grade of any student for the semester. Method `getMaximum` (lines 73–91) determines the highest grade of any student for the semester. Method `getAverage` (lines 94–104) determines a particular student's semester average. Method `outputBarChart` (lines 107–137) outputs a grade bar chart for the entire semester's student grades. Method `outputGrades` (lines 140–164) outputs the array in a tabular format, along with each student's semester average.

160         // pass row of grades as the argument to getAverage
161         double average = getAverage( grades[ student ] );
162         System.out.printf( "%9.2f\n", average );
163     } // end outer for
164 } // end method outputGrades
165 } // end class GradeBook
```

**Fig. 7.18** | GradeBook class using a two-dimensional array to store grades. (Part 4 of 4.)

### *Methods getMinimum and getMaximum*

Methods `getMinimum`, `getMaximum`, `outputBarChart` and `outputGrades` each loop through array `grades` by using nested `for` statements—for example, the nested enhanced `for` statement from the declaration of method `getMinimum` (lines 58–67). The outer enhanced `for` statement iterates through the two-dimensional array `grades`, assigning successive rows to parameter `studentGrades` on successive iterations. The square brackets following the parameter name indicate that `studentGrades` refers to a one-dimensional `int` array—namely, a row in array `grades` containing one student’s grades. To find the lowest overall grade, the inner `for` statement compares the elements of the current one-dimensional array `studentGrades` to variable `lowGrade`. For example, on the first iteration of the outer `for`, row 0 of `grades` is assigned to parameter `studentGrades`. The inner enhanced `for` statement then loops through `studentGrades` and compares each grade value with `lowGrade`. If a grade is less than `lowGrade`, `lowGrade` is set to that grade. On the second iteration of the outer enhanced `for` statement, row 1 of `grades` is assigned to `studentGrades`, and the elements of this row are compared with variable `lowGrade`. This repeats until all rows of `grades` have been traversed. When execution of the nested statement is complete, `lowGrade` contains the lowest grade in the two-dimensional array. Method `getMaximum` works similarly to method `getMinimum`.

### *Method outputBarChart*

Method `outputBarChart` in Fig. 7.18 is nearly identical to the one in Fig. 7.14. However, to output the overall grade distribution for a whole semester, the method here uses nested enhanced `for` statements (lines 115–119) to create the one-dimensional array `frequency`

based on all the grades in the two-dimensional array. The rest of the code in each of the two `outputBarChart` methods that displays the chart is identical.

### *Method outputGrades*

Method `outputGrades` (lines 140–164) uses nested `for` statements to output values of the array `grades` and each student’s semester average. The output (Fig. 7.19) shows the result, which resembles the tabular format of a professor’s physical grade book. Lines 146–147 print the column headings for each test. We use a counter-controlled `for` statement here so that we can identify each test with a number. Similarly, the `for` statement in lines 152–163 first outputs a row label using a counter variable to identify each student (line 154). Although array indices start at 0, lines 147 and 154 output `test + 1` and `student + 1`, respectively, to produce test and student numbers starting at 1 (see Fig. 7.19). The inner `for` statement (lines 156–157) uses the outer `for` statement’s counter variable `student` to loop through a specific row of array `grades` and output each student’s test grade. An enhanced `for` statement can be nested in a counter-controlled `for` statement, and vice versa. Finally, line 161 obtains each student’s semester average by passing the current row of `grades` (i.e., `grades[student]`) to method `getAverage`.

### *Method getAverage*

Method `getAverage` (lines 94–104) takes one argument—a one-dimensional array of test results for a particular student. When line 161 calls `getAverage`, the argument is `grades[student]`, which specifies that a particular row of the two-dimensional array `grades` should be passed to `getAverage`. For example, based on the array created in Fig. 7.19, the argument `grades[1]` represents the three values (a one-dimensional array of `grades`) stored in row 1 of the two-dimensional array `grades`. Recall that a two-dimensional array is one whose elements are one-dimensional arrays. Method `getAverage` calculates the sum of the array elements, divides the total by the number of test results and returns the floating-point result as a `double` value (line 103).

### *Class GradeBookTest That Demonstrates Class GradeBook*

Figure 7.19 creates an object of class `GradeBook` (Fig. 7.18) using the two-dimensional array of `ints` named `gradesArray` (declared and initialized in lines 10–19). Lines 21–22 pass a course name and `gradesArray` to the `GradeBook` constructor. Lines 23–24 then invoke `myGradeBook`’s `displayMessage` and `processGrades` methods to display a welcome message and obtain a report summarizing the students’ grades for the semester, respectively.

## 7.11 Variable-Length Argument Lists

With **variable-length argument lists**, you can create methods that receive an unspecified number of arguments. A type followed by an **ellipsis** (`...`) in a method's parameter list indicates that the method receives a variable number of arguments of that particular type. This use of the ellipsis can occur only once in a parameter list, and the ellipsis, together with its type, must be placed at the end of the parameter list. While you can use method overloading and array passing to accomplish much of what is accomplished with variable-length argument lists, using an ellipsis in a method's parameter list is more concise.

Figure 7.20 demonstrates method `average` (lines 7–16), which receives a variable-length sequence of `double`s. Java treats the variable-length argument list as an array whose elements are all of the same type. Hence, the method body can manipulate the parameter numbers as an array of `double`s. Lines 12–13 use the enhanced for loop to walk through the array and calculate the total of the `double`s in the array. Line 15 accesses `numbers.length` to obtain the size of the `numbers` array for use in the averaging calculation. Lines 29, 31 and 33 in `main` call method `average` with two, three and four arguments, respectively. Method `average` has a variable-length argument list (line 7), so it can average as many `double` arguments as the caller passes. The output shows that each call to method `average` returns the correct value.

---

```

2 // Using variable-length argument lists.
3
4 public class VarargsTest
5 {
6     // calculate average
7     public static double average( double... numbers )
8     {
9         double total = 0.0; // initialize total
10
11         // calculate total using the enhanced for statement
12         for ( double d : numbers )
13             total += d;
14
15         return total / numbers.length;
16     } // end method average
17
18     public static void main( String[] args )
19     {
20         double d1 = 10.0;
21         double d2 = 20.0;
22         double d3 = 30.0;
23         double d4 = 40.0;
24
25         System.out.printf( "d1 = %.1f\n d2 = %.1f\n d3 = %.1f\n d4 = %.1f\n\n",
26                             d1, d2, d3, d4 );
27
28         System.out.printf( "Average of d1 and d2 is %.1f\n",
29                             average( d1, d2 ) );

```

**Fig. 7.20** | Using variable-length argument lists. (Part I of 2.)

```

30     System.out.printf( "Average of d1, d2 and d3 is %.1f\n",
31         average( d1, d2, d3 ) );
32     System.out.printf( "Average of d1, d2, d3 and d4 is %.1f\n",
33         average( d1, d2, d3, d4 ) );
34     } // end main
35 } // end class VarargsTest

```

```

d1 = 10.0
d2 = 20.0
d3 = 30.0
d4 = 40.0

```

```

Average of d1 and d2 is 15.0
Average of d1, d2 and d3 is 20.0
Average of d1, d2, d3 and d4 is 25.0

```

**Fig. 7.20** | Using variable-length argument lists. (Part 2 of 2.)

### Common Programming Error 7.6

*Placing an ellipsis indicating a variable-length argument list in the middle of a parameter list is a syntax error. An ellipsis may be placed only at the end of the parameter list.*

## 7.12 Using Command-Line Arguments

It's possible to pass arguments from the command line (these are known as **command-line arguments**) to an application by including a parameter of type `String[]` (i.e., an array of `Strings`) in the parameter list of `main`, exactly as we've done in every application in the book. By convention, this parameter is named `args`. When an application is executed using the `java` command, Java passes the command-line arguments that appear after the class name in the `java` command to the application's `main` method as `Strings` in the array `args`. The number of command-line arguments is obtained by accessing the array's `length` attribute. Common uses of command-line arguments include passing options and file names to applications.

Our next example uses command-line arguments to determine the size of an array, the value of its first element and the increment used to calculate the values of the array's remaining elements. The command

```
java InitArray 5 0 4
```

passes three arguments, 5, 0 and 4, to the application `InitArray`. Command-line arguments are separated by white space, not commas. When this command executes, `InitArray`'s `main` method receives the three-element array `args` (i.e., `args.length` is 3) in which `args[0]` contains the `String` "5", `args[1]` contains the `String` "0" and `args[2]` contains the `String` "4". The program determines how to use these arguments—in Fig. 7.21 we convert the three command-line arguments to `int` values and use them to initialize an array. When the program executes, if `args.length` is not 3, the program prints an error message and terminates (lines 9–12). Otherwise, lines 14–32 initialize and display the array based on the values of the command-line arguments.

Line 16 gets `args[0]`—a `String` that specifies the array size—and converts it to an `int` value that the program uses to create the array in line 17. The static method `parseInt` of class `Integer` converts its `String` argument to an `int`.

```

1 // Fig. 7.21: InitArray.java
2 // Initializing an array using command-line arguments.
3
4 public class InitArray
5 {
6     public static void main( String[] args )
7     {
8         // check number of command-line arguments
9         if ( args.length != 3 )
10            System.out.println(
11                "Error: Please re-enter the entire command, including\n" +
12                "an array size, initial value and increment." );
13        else
14        {
15            // get array size from first command-line argument
16            int arrayLength = Integer.parseInt( args[ 0 ] );
17            int[] array = new int[ arrayLength ]; // create array
18
19            // get initial value and increment from command-line arguments
20            int initialValue = Integer.parseInt( args[ 1 ] );
21            int increment = Integer.parseInt( args[ 2 ] );
22
23            // calculate value for each array element
24            for ( int counter = 0; counter < array.length; counter++ )
25                array[ counter ] = initialValue + increment * counter;
26
27            System.out.printf( "%s%8s\n", "Index", "Value" );
28
29            // display array index and value
30            for ( int counter = 0; counter < array.length; counter++ )
31                System.out.printf( "%5d%8d\n", counter, array[ counter ] );
32        } // end else
33    } // end main
34 } // end class InitArray

```

```
java InitArray
```

```
Error: Please re-enter the entire command, including
an array size, initial value and increment.
```

```
java InitArray 5 0 4
```

| Index | Value |
|-------|-------|
| 0     | 0     |
| 1     | 4     |
| 2     | 8     |
| 3     | 12    |
| 4     | 16    |

**Fig. 7.21** | Initializing an array using command-line arguments. (Part 1 of 2.)

```

java InitArray 8 1 2
Index  Value
  0     1
  1     3
  2     5
  3     7
  4     9
  5    11
  6    13
  7    15

```

**Fig. 7.21** | Initializing an array using command-line arguments. (Part 2 of 2.)

Lines 20–21 convert the `args[1]` and `args[2]` command-line arguments to `int` values and store them in `initialValue` and `increment`, respectively. Lines 24–25 calculate the value for each array element.

The output of the first execution shows that the application received an insufficient number of command-line arguments. The second execution uses command-line arguments 5, 0 and 4 to specify the size of the array (5), the value of the first element (0) and the increment of each value in the array (4), respectively. The corresponding output shows that these values create an array containing the integers 0, 4, 8, 12 and 16. The output from the third execution shows that the command-line arguments 8, 1 and 2 produce an array whose 8 elements are the nonnegative odd integers from 1 to 15.

## 7.13 Class Arrays

Class **Arrays** helps you avoid reinventing the wheel by providing static methods for common array manipulations. These methods include **sort** for sorting an array (i.e., arranging elements into increasing order), **binarySearch** for searching an array (i.e., determining whether an array contains a specific value and, if so, where the value is located), **equals** for comparing arrays and **fill** for placing values into an array. These methods are overloaded for primitive-type arrays and for arrays of objects. Our focus in this section is on using the built-in capabilities provided by the Java API. Chapter 19, Searching, Sorting and Big O, shows how to implement your own sorting and searching algorithms, which are of great interest to computer-science researchers and students.

Figure 7.22 uses `Arrays` methods `sort`, `binarySearch`, `equals` and `fill`, and shows how to copy arrays with class `System`'s static **arraycopy method**. In `main`, line 11 sorts the elements of array `doubleArray`. The static method `sort` of class `Arrays` orders the array's elements in *ascending* order by default. We discuss how to sort in *descending* order later in the chapter. Overloaded versions of `sort` allow you to sort a specific range of elements. Lines 12–15 output the sorted array.

```

1 // Fig. 7.22: ArrayManipulations.java
2 // Arrays class methods and System.arraycopy.
3 import java.util.Arrays;
4

```

**Fig. 7.22** | `Arrays` class methods. (Part 1 of 3.)

```
5 public class ArrayManipulations
6 {
7     public static void main( String[] args )
8     {
9         // sort doubleArray into ascending order
10        double[] doubleArray = { 8.4, 9.3, 0.2, 7.9, 3.4 };
11        Arrays.sort( doubleArray );
12        System.out.printf( "\ndoubleArray: " );
13
14        for ( double value : doubleArray )
15            System.out.printf( "%.1f ", value );
16
17        // fill 10-element array with 7s
18        int[] filledIntArray = new int[ 10 ];
19        Arrays.fill( filledIntArray, 7 );
20        displayArray( filledIntArray, "filledIntArray" );
21
22        // copy array intArray into array intArrayCopy
23        int[] intArray = { 1, 2, 3, 4, 5, 6 };
24        int[] intArrayCopy = new int[ intArray.length ];
25        System.arraycopy( intArray, 0, intArrayCopy, 0, intArray.length );
26        displayArray( intArray, "intArray" );
27        displayArray( intArrayCopy, "intArrayCopy" );
28
29        // compare intArray and intArrayCopy for equality
30        boolean b = Arrays.equals( intArray, intArrayCopy );
31        System.out.printf( "\n\nintArray %s intArrayCopy\n",
32            ( b ? "==" : "!=" ) );
33
34        // compare intArray and filledIntArray for equality
35        b = Arrays.equals( intArray, filledIntArray );
36        System.out.printf( "intArray %s filledIntArray\n",
37            ( b ? "==" : "!=" ) );
38
39        // search intArray for the value 5
40        int location = Arrays.binarySearch( intArray, 5 );
41
42        if ( location >= 0 )
43            System.out.printf(
44                "Found 5 at element %d in intArray\n", location );
45        else
46            System.out.println( "5 not found in intArray" );
47
48        // search intArray for the value 8763
49        location = Arrays.binarySearch( intArray, 8763 );
50
51        if ( location >= 0 )
52            System.out.printf(
53                "Found 8763 at element %d in intArray\n", location );
54        else
55            System.out.println( "8763 not found in intArray" );
56    } // end main
57 }
```

**Fig. 7.22** | Arrays class methods. (Part 2 of 3.)

```

58 // output values in each array
59 public static void displayArray( int[] array, String description )
60 {
61     System.out.printf( "\n%s: ", description );
62
63     for ( int value : array )
64         System.out.printf( "%d ", value );
65 } // end method displayArray
66 } // end class ArrayManipulations

```

```

doubleArray: 0.2 3.4 7.9 8.4 9.3
filledIntArray: 7 7 7 7 7 7 7 7 7
intArray: 1 2 3 4 5 6
intArrayCopy: 1 2 3 4 5 6

intArray == intArrayCopy
intArray != filledIntArray
Found 5 at element 4 in intArray
8763 not found in intArray

```

**Fig. 7.22** | Arrays class methods. (Part 3 of 3.)

Line 19 calls static method `fill` of class `Arrays` to populate all 10 elements of `filledIntArray` with 7s. Overloaded versions of `fill` allow you to populate a specific range of elements with the same value. Line 20 calls our class's `displayArray` method (declared at lines 59–65) to output the contents of `filledIntArray`.

Line 25 copies the elements of `intArray` into `intArrayCopy`. The first argument (`intArray`) passed to `System` method `arraycopy` is the array from which elements are to be copied. The second argument (0) is the index that specifies the starting point in the range of elements to copy from the array. This value can be any valid array index. The third argument (`intArrayCopy`) specifies the destination array that will store the copy. The fourth argument (0) specifies the index in the destination array where the first copied element should be stored. The last argument specifies the number of elements to copy from the array in the first argument. In this case, we copy all the elements in the array.

Lines 30 and 35 call static method `equals` of class `Arrays` to determine whether all the elements of two arrays are equivalent. If the arrays contain the same elements in the same order, the method returns `true`; otherwise, it returns `false`.

Lines 40 and 49 call static method `binarySearch` of class `Arrays` to perform a binary search on `intArray`, using the second argument (5 and 8763, respectively) as the key. If `value` is found, `binarySearch` returns the index of the element; otherwise, `binarySearch` returns a negative value. The negative value returned is based on the search key's insertion point—the index where the key would be inserted in the array if we were performing an insert operation. After `binarySearch` determines the insertion point, it changes its sign to negative and subtracts 1 to obtain the return value. For example, in Fig. 7.22, the insertion point for the value 8763 is the element with index 6 in the array. Method `binarySearch` changes the insertion point to -6, subtracts 1 from it and returns the value -7. Subtracting 1 from the insertion point guarantees that method `binarySearch` returns positive values ( $\geq 0$ ) if and only if the key is found. This return value is useful for inserting elements in a sorted array. Chapter 19 discusses binary searching in detail.

### Common Programming Error 7.7

Passing an unsorted array to `binarySearch` is a logic error—the value returned is undefined.

## 7.14 Introduction to Collections and Class `ArrayList`

The Java API provides several predefined data structures, called **collections**, used to store groups of related objects. These classes provide efficient methods that organize, store and retrieve your data without requiring knowledge of how the data is being stored. This reduces application-development time.

You've used arrays to store sequences of objects. Arrays do not automatically change their size at execution time to accommodate additional elements. The collection class `ArrayList<T>` (from package `java.util`) provides a convenient solution to this problem—it can *dynamically* change its size to accommodate more elements. The `T` (by convention) is a *placeholder*—when declaring a new `ArrayList`, replace it with the type of elements that you want the `ArrayList` to hold. This is similar to specifying the type when declaring an array, except that *only nonprimitive types can be used with these collection classes*. For example,

```
ArrayList<String> list;
```

declares `list` as an `ArrayList` collection that can store only `Strings`. Classes with this kind of placeholder that can be used with any type are called **generic classes**. Additional generic collection classes and generics are discussed in Chapters 20 and 21, respectively. Figure 7.23 shows some common methods of class `ArrayList<T>`.

| Method                  | Description                                                                                            |
|-------------------------|--------------------------------------------------------------------------------------------------------|
| <code>add</code>        | Adds an element to the end of the <code>ArrayList</code> .                                             |
| <code>clear</code>      | Removes all the elements from the <code>ArrayList</code> .                                             |
| <code>contains</code>   | Returns true if the <code>ArrayList</code> contains the specified element; otherwise, returns false.   |
| <code>get</code>        | Returns the element at the specified index.                                                            |
| <code>indexOf</code>    | Returns the index of the first occurrence of the specified element in the <code>ArrayList</code> .     |
| <code>remove</code>     | Overloaded. Removes the first occurrence of the specified value or the element at the specified index. |
| <code>size</code>       | Returns the number of elements stored in the <code>ArrayList</code> .                                  |
| <code>trimToSize</code> | Trims the capacity of the <code>ArrayList</code> to current number of elements.                        |

**Fig. 7.23** | Some methods and properties of class `ArrayList<T>`.

Figure 7.24 demonstrates some common `ArrayList` capabilities. Line 10 creates a new empty `ArrayList` of `Strings` with a default initial capacity of 10 elements. The capacity indicates how many items the `ArrayList` can hold without growing. `ArrayList` is implemented using an array behind the scenes. When the `ArrayList` grows, it must create a larger internal array and copy each element to the new array. This is a time-con-

suming operation. It would be inefficient for the ArrayList to grow each time an element is added. Instead, it grows only when an element is added *and* the number of elements is equal to the capacity—i.e., there's no space for the new element.

---

```

1 // Fig. 7.24: ArrayListCollection.java
2 // Generic ArrayList<T> collection demonstration.
3 import java.util.ArrayList;
4
5 public class ArrayListCollection
6 {
7     public static void main( String[] args )
8     {
9         // create a new ArrayList of Strings with an initial capacity of 10
10        ArrayList< String > items = new ArrayList< String >();
11
12        items.add( "red" ); // append an item to the list
13        items.add( 0, "yellow" ); // insert the value at index 0
14
15        // header
16        System.out.print(
17            "Display list contents with counter-controlled loop:" );
18
19        // display the colors in the list
20        for ( int i = 0; i < items.size(); i++ )
21            System.out.printf( " %s", items.get( i ) );
22
23        // display colors using foreach in the display method
24        display( items,
25            "\nDisplay list contents with enhanced for statement:" );
26
27        items.add( "green" ); // add "green" to the end of the list
28        items.add( "yellow" ); // add "yellow" to the end of the list
29        display( items, "List with two new elements:" );
30
31        items.remove( "yellow" ); // remove the first "yellow"
32        display( items, "Remove first instance of yellow:" );
33
34        items.remove( 1 ); // remove item at index 1
35        display( items, "Remove second list element (green):" );
36
37        // check if a value is in the List
38        System.out.printf( "\n\"red\" is %sin the list\n",
39            items.contains( "red" ) ? "" : "not " );
40
41        // display number of elements in the List
42        System.out.printf( "Size: %s\n", items.size() );
43    } // end main
44
45    // display the ArrayList's elements on the console
46    public static void display( ArrayList< String > items, String header )
47    {
48        System.out.print( header ); // display header

```

49
50     // display each element in items
51     for ( String item : items )
52         System.out.printf( " %s", item );
53
54     System.out.println(); // display end of line
55 } // end method display
56 } // end class ArrayListCollection

```

```

Display list contents with counter-controlled loop: yellow red
Display list contents with enhanced for statement: yellow red
List with two new elements: yellow red green yellow
Remove first instance of yellow: red green yellow
Remove second list element (green): red yellow
"red" is in the list
Size: 2

```

**Fig. 7.24** | Generic `ArrayList<T>` collection demonstration. (Part 2 of 2.)

The **add** method adds elements to the `ArrayList` (lines 12–13). The `add` method with *one* argument appends its argument to the end of the `ArrayList`. The `add` method with *two* arguments inserts a new element at the specified position. The first argument is an index. As with arrays, collection indices start at zero. The second argument is the value to insert at that index. The indices of all subsequent elements are incremented by one. Inserting an element is usually slower than adding an element to the end of the `ArrayList`.

Lines 20–21 display the items in the `ArrayList`. The **size** method returns the number of elements currently in the `ArrayList`. `ArrayList`'s method **get** (line 21) obtains the element at a specified index. Lines 24–25 display the elements again by invoking method `display` (defined at lines 46–55). Lines 27–28 add two more elements to the `ArrayList`, then line 29 displays the elements again to confirm that the two elements were added to the end of the collection.

The **remove** method is used to remove an element with a specific value (line 31). It removes only the first such element. If no such element is in the `ArrayList`, `remove` does nothing. An overloaded version of the method removes the element at the specified index (line 34). When an element is removed, the indices of all elements after the removed element decrease by one.

Line 39 uses the **contains** method to check if an item is in the `ArrayList`. The `contains` method returns `true` if the element is found in the `ArrayList`, and `false` otherwise. The method compares its argument to each element of the `ArrayList` in order, so using `contains` on a large `ArrayList` can be inefficient. Line 42 displays the `ArrayList`'s size.

## 7.15 (Optional) GUI and Graphics Case Study: Drawing Arcs

Using Java's graphics features, we can create complex drawings that would be more tedious to code line by line. In Figs. 7.25–7.26, we use arrays and repetition statements to draw a rainbow by using `Graphics` method `fillArc`. Drawing arcs in Java is similar to drawing ovals—an arc is simply a section of an oval.

Figure 7.25 begins with the usual `import` statements for creating drawings (lines 3–5). Lines 10–11 declare and create two new color constants—`VIOLET` and `INDIGO`. As you may know, the colors of a rainbow are red, orange, yellow, green, blue, indigo and violet. Java has predefined constants only for the first five colors. Lines 15–17 initialize an array with the colors of the rainbow, starting with the innermost arcs first. The array begins with two `Color.WHITE` elements, which, as you’ll soon see, are for drawing the empty arcs at the center of the rainbow. The instance variables can be initialized when they’re declared, as shown in lines 10–17. The constructor (lines 20–23) contains a single statement that calls method `setBackground` (which is inherited from class `JPanel`) with the parameter `Color.WHITE`. Method `setBackground` takes a single `Color` argument and sets the background of the component to that color.

---

```

1 // Fig. 7.25: DrawRainbow.java
2 // Demonstrates using colors in an array.
3 import java.awt.Color;
4 import java.awt.Graphics;
5 import javax.swing.JPanel;
6
7 public class DrawRainbow extends JPanel
8 {
9     // define indigo and violet
10    private final static Color VIOLET = new Color( 128, 0, 128 );
11    private final static Color INDIGO = new Color( 75, 0, 130 );
12
13    // colors to use in the rainbow, starting from the innermost
14    // The two white entries result in an empty arc in the center
15    private Color[] colors =
16        { Color.WHITE, Color.VIOLET, Color.INDIGO, Color.BLUE,
17          Color.GREEN, Color.YELLOW, Color.ORANGE, Color.RED };
18
19    // constructor
20    public DrawRainbow()
21    {
22        setBackground( Color.WHITE ); // set the background to white
23    } // end DrawRainbow constructor
24
25    // draws a rainbow using concentric arcs
26    public void paintComponent( Graphics g )
27    {
28        super.paintComponent( g );
29
30        int radius = 20; // radius of an arc
31
32        // draw the rainbow near the bottom-center
33        int centerX = getWidth() / 2;
34        int centerY = getHeight() - 10;
35
36        // draws filled arcs starting with the outermost
37        for ( int counter = colors.length; counter > 0; counter-- )
38        {

```

---

**Fig. 7.25** | Drawing a rainbow using arcs and an array of colors. (Part I of 2.)

---

```

39         // set the color for the current arc
40         g.setColor( colors[ counter - 1 ] );
41
42         // fill the arc from 0 to 180 degrees
43         g.fillArc( centerX - counter * radius,
44                 centerY - counter * radius,
45                 counter * radius * 2, counter * radius * 2, 0, 180 );
46     } // end for
47 } // end method paintComponent
48 } // end class DrawRainbow

```

---

**Fig. 7.25** | Drawing a rainbow using arcs and an array of colors. (Part 2 of 2.)

Line 30 in `paintComponent` declares local variable `radius`, which determines the radius of each arc. Local variables `centerX` and `centerY` (lines 33–34) determine the location of the midpoint on the base of the rainbow. The loop at lines 37–46 uses control variable `counter` to count backward from the end of the array, drawing the largest arcs first and placing each successive smaller arc on top of the previous one. Line 40 sets the color to draw the current arc from the array. The reason we have `Color.WHITE` entries at the beginning of the array is to create the empty arc in the center. Otherwise, the center of the rainbow would just be a solid violet semicircle. [*Note:* You can change the individual colors and the number of entries in the array to create new designs.]

The `fillArc` method call at lines 43–45 draws a filled semicircle. Method `fillArc` requires six parameters. The first four represent the bounding rectangle in which the arc will be drawn. The first two of these specify the coordinates for the upper-left corner of the bounding rectangle, and the next two specify its width and height. The fifth parameter is the starting angle on the oval, and the sixth specifies the **sweep**, or the amount of arc to cover. The starting angle and sweep are measured in degrees, with zero degrees pointing right. A positive sweep draws the arc counterclockwise, while a negative sweep draws the arc clockwise. A method similar to `fillArc` is `drawArc`—it requires the same parameters as `fillArc`, but draws the edge of the arc rather than filling it.

Class `DrawRainbowTest` (Fig. 7.26) creates and sets up a `JFrame` to display the rainbow. Once the program makes the `JFrame` visible, the system calls the `paintComponent` method in class `DrawRainbow` to draw the rainbow on the screen.

---

```

1 // Fig. 7.26: DrawRainbowTest.java
2 // Test application to display a rainbow.
3 import javax.swing.JFrame;
4
5 public class DrawRainbowTest
6 {
7     public static void main( String[] args )
8     {
9         DrawRainbow panel = new DrawRainbow();
10        JFrame application = new JFrame();
11
12        application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );

```

---

**Fig. 7.26** | Creating `JFrame` to display a rainbow. (Part 1 of 2.)

```

13     application.add( panel );
14     application.setSize( 400, 250 );
15     application.setVisible( true );
16 } // end main
17 } // end class DrawRainbowTest

```

**Fig. 7.26** | Creating JFrame to display a rainbow. (Part 2 of 2.)

### GUI and Graphics Case Study Exercise

- 7.1** (*Drawing Spirals*) In this exercise, you'll draw spirals with methods `drawLine` and `drawArc`.
- Draw a square-shaped spiral (as in the left screen capture of Fig. 7.27), centered on the panel, using method `drawLine`. One technique is to use a loop that increases the line length after drawing every second line. The direction in which to draw the next line should follow a distinct pattern, such as down, left, up, right.
  - Draw a circular spiral (as in the right screen capture of Fig. 7.27), using method `drawArc` to draw one semicircle at a time. Each successive semicircle should have a larger radius (as specified by the bounding rectangle's width) and should continue drawing where the previous semicircle finished.

**Fig. 7.27** | Drawing a spiral using `drawLine` (left) and `drawArc` (right).

## 7.16 Wrap-Up

This chapter began our introduction to data structures, exploring the use of arrays to store data in and retrieve data from lists and tables of values. The chapter examples demonstrated

how to declare an array, initialize an array and refer to individual elements of an array. The chapter introduced the enhanced `for` statement to iterate through arrays. We used exception handling to test for `ArrayIndexOutOfBoundsException`s that occur when a program attempts to access an array element outside the bounds of an array. We also illustrated how to pass arrays to methods and how to declare and manipulate multidimensional arrays. Finally, the chapter showed how to write methods that use variable-length argument lists and how to read arguments passed to a program from the command line.

We introduced the `ArrayList<T>` generic collection, which provides all the functionality and performance of arrays, along with other useful capabilities such as dynamic resizing. We used the `add` methods to add new items to the end of an `ArrayList` and to insert items in an `ArrayList`. The `remove` method was used to remove the first occurrence of a specified item, and an overloaded version of `remove` was used to remove an item at a specified index. We used the `size` method to obtain number of items in the `ArrayList`.

We continue our coverage of data structures in Chapter 20, *Generic Collections*. Chapter 20 introduces the Java Collections Framework, which uses generics to allow you to specify the exact types of objects that a particular data structure will store. Chapter 20 also introduces Java's other predefined data structures. The Collections API provides class `Arrays`, which contains utility methods for array manipulation. Chapter 20 uses several static methods of class `Arrays` to perform such manipulations as sorting and searching the data in an array. You'll be able to use some of the `Arrays` methods discussed in Chapter 20 after reading the current chapter, but some of the `Arrays` methods require knowledge of concepts presented later in the book. Chapter 21 presents the topic of generics, which provide the means to create general models of methods and classes that can be declared once, but used with many different data types. Chapter 22, *Custom Generic Data Structures*, shows how to build dynamic data structures, such as lists, queues, stacks and trees, that can grow and shrink as programs execute.

We've now introduced the basic concepts of classes, objects, control statements, methods, arrays and collections. In Chapter 8, we take a deeper look at classes and objects.

---

## Summary

### *Section 7.1 Introduction*

- Arrays (p. 241) are fixed-length data structures consisting of related data items of the same type.

### *Section 7.2 Arrays*

- An array is a group of variables (called elements or components; p. 242) containing values that all have the same type. Arrays are objects, so they're considered reference types.
- A program refers to any one of an array's elements with an array-access expression (p. 242) that includes the name of the array followed by the index of the particular element in square brackets (`[]`; p. 242).
- The first element in every array has index zero (p. 242) and is sometimes called the zeroth element.
- An index must be a nonnegative integer. A program can use an expression as an index.
- An array object knows its own length and stores this information in a `length` instance variable (p. 242).

### Section 7.3 Declaring and Creating Arrays

- To create an array object, specify the array's element type and the number of elements as part of an array-creation expression (p. 243) that uses keyword `new`.
- When an array is created, each element receives a default value—zero for numeric primitive-type elements, `false` for boolean elements and `null` for references.
- In an array declaration, the type and the square brackets can be combined at the beginning of the declaration to indicate that all the identifiers in the declaration are array variables.
- Every element of a primitive-type array contains a variable of the array's declared type. Every element of a reference-type array is a reference to an object of the array's declared type.

### Section 7.4 Examples Using Arrays

- A program can create an array and initialize its elements with an array initializer (p. 245).
- Constant variables (p. 247) are declared with keyword `final`, must be initialized before they're used and cannot be modified thereafter.
- When a Java program executes, the JVM checks array indices to ensure that they're greater than or equal to 0 and less than the array's length. If a program uses an invalid index, Java generates an exception (p. 253) to indicate that an error occurred in the program at execution time.
- When a program is executed, array element indices are checked for validity—all indices must be greater than or equal to 0 and less than the length of the array. If an attempt is made to use an invalid index to access an element, an `ArrayIndexOutOfBoundsException` (p. 253) exception occurs.
- An exception indicates a problem that occurs while a program executes. The name “exception” suggests that the problem occurs infrequently—if the “rule” is that a statement normally executes correctly, then the problem represents the “exception to the rule.”
- Exception handling (p. 253) enables you to create fault-tolerant programs.
- To handle an exception, place any code that might throw an exception (p. 253) in a try statement.
- The try block (p. 253) contains the code that might throw an exception, and the catch block (p. 253) contains the code that handles the exception if one occurs.
- You can have many catch blocks to handle different types of exceptions that might be thrown in the corresponding try block.
- When a try block terminates, any variables declared in the try block go out of scope.
- A catch block declares a type and an exception parameter. Inside the catch block, you can use the parameter's identifier to interact with a caught exception object.
- An exception object's `toString` method returns the exception's error message.

### Section 7.5 Case Study: Card Shuffling and Dealing Simulation

- The `toString` method of an object is called implicitly when the object is used where a `String` is expected (e.g., when `printf` outputs the object as a `String` using the `%s` format specifier or when the object is concatenated to a `String` using the `+` operator).

### Section 7.6 Enhanced for Statement

- The enhanced for statement (p. 258) allows you to iterate through the elements of an array or a collection without using a counter. The syntax of an enhanced for statement is:

```
for ( parameter : arrayName )
    statement
```

where *parameter* has a type and an identifier (e.g., `int number`), and *arrayName* is the array through which to iterate.

- The enhanced for statement cannot be used to modify elements in an array. If a program needs to modify elements, use the traditional counter-controlled for statement.

### Section 7.7 Passing Arrays to Methods

- When an argument is passed by value, a copy of the argument's value is made and passed to the called method. The called method works exclusively with the copy.
- When an argument is passed by reference (p. 262), the called method can access the argument's value in the caller directly and possibly modify it.
- All arguments in Java are passed by value. A method call can pass two types of values to a method—copies of primitive values and copies of references to objects. Although an object's reference is passed by value (p. 262), a method can still interact with the referenced object by calling its `public` methods using the copy of the object's reference.
- To pass an object reference to a method, simply specify in the method call the name of the variable that refers to the object.
- When you pass an array or an individual array element of a reference type to a method, the called method receives a copy of the array or element's reference. When you pass an individual element of a primitive type, the called method receives a copy of the element's value.
- To pass an individual array element to a method, use the indexed name of the array.

### Section 7.9 Multidimensional Arrays

- Multidimensional arrays with two dimensions are often used to represent tables of values consisting of information arranged in rows and columns.
- A two-dimensional array (p. 268) with  $m$  rows and  $n$  columns is called an  $m$ -by- $n$  array. Such an array can be initialized with an array initializer of the form

```
arrayType[][] arrayName = { { row1 initializer }, { row2 initializer }, ... };
```

- Multidimensional arrays are maintained as arrays of separate one-dimensional arrays. As a result, the lengths of the rows in a two-dimensional array are not required to be the same.
- A multidimensional array with the same number of columns in every row can be created with an array-creation expression of the form

```
arrayType[][] arrayName = new arrayType[ numRows ][ numColumns ];
```

### Section 7.11 Variable-Length Argument Lists

- An argument type followed by an ellipsis (`...`; p. 278) in a method's parameter list indicates that the method receives a variable number of arguments of that particular type. The ellipsis can occur only once in a method's parameter list. It must be at the end of the parameter list.
- A variable-length argument list (p. 278) is treated as an array within the method body. The number of arguments in the array can be obtained using the array's `length` field.

### Section 7.12 Using Command-Line Arguments

- Passing arguments to `main` (p. 279) from the command line is achieved by including a parameter of type `String[]` in the parameter list of `main`. By convention, `main`'s parameter is named `args`.
- Java passes command-line arguments that appear after the class name in the `java` command to the application's `main` method as `Strings` in the array `args`.

### Section 7.13 Class Arrays

- Class `Arrays` (p. 281) provides static methods that perform common array manipulations, including `sort` to sort an array, `binarySearch` to search a sorted array, `equals` to compare arrays and `fill` to place items in an array.

- Class `System`'s `arraycopy` method (p. 281) enables you to copy the elements of one array into another.

### Section 7.14 Introduction to Collections and Class `ArrayList`

- The Java API's collection classes provide efficient methods that organize, store and retrieve data without requiring knowledge of how the data is being stored.
- An `ArrayList<T>` (p. 284) is similar to an array, but can be dynamically resized.
- The `add` method (p. 286) with one argument appends an element to the end of an `ArrayList`.
- The `add` method with two arguments inserts a new element at a specified position in an `ArrayList`.
- The `size` method (p. 286) returns the number of elements currently in an `ArrayList`.
- The `remove` method with a reference to an object as an argument removes the first element that matches the argument's value.
- The `remove` method with an integer argument removes the element at the specified index, and all elements above that index are shifted down by one.
- The `contains` method returns `true` if the element is found in the `ArrayList`, and `false` otherwise.

## Self-Review Exercises

- 7.1** Fill in the blank(s) in each of the following statements:
- Lists and tables of values can be stored in \_\_\_\_\_.
  - An array is a group of \_\_\_\_\_ (called elements or components) containing values that all have the same \_\_\_\_\_.
  - The \_\_\_\_\_ allows you to iterate through the elements in an array without using a counter.
  - The number used to refer to a particular array element is called the element's \_\_\_\_\_.
  - An array that uses two indices is referred to as a(n) \_\_\_\_\_ array.
  - Use the enhanced `for` statement \_\_\_\_\_ to walk through double array numbers.
  - Command-line arguments are stored in \_\_\_\_\_.
  - Use the expression \_\_\_\_\_ to receive the total number of arguments in a command line. Assume that command-line arguments are stored in `String[] args`.
  - Given the command `java MyClass test`, the first command-line argument is \_\_\_\_\_.
  - A(n) \_\_\_\_\_ in the parameter list of a method indicates that the method can receive a variable number of arguments.
- 7.2** Determine whether each of the following is *true* or *false*. If *false*, explain why.
- An array can store many different types of values.
  - An array index should normally be of type `float`.
  - An individual array element that's passed to a method and modified in that method will contain the modified value when the called method completes execution.
  - Command-line arguments are separated by commas.
- 7.3** Perform the following tasks for an array called `fractions`:
- Declare a constant `ARRAY_SIZE` that's initialized to 10.
  - Declare an array with `ARRAY_SIZE` elements of type `double`, and initialize the elements to 0.
  - Refer to array element 4.
  - Assign the value 1.667 to array element 9.
  - Assign the value 3.333 to array element 6.
  - Sum all the elements of the array, using a `for` statement. Declare the integer variable `x` as a control variable for the loop.
- 7.4** Perform the following tasks for an array called `table`:

- a) Declare and create the array as an integer array that has three rows and three columns. Assume that the constant `ARRAY_SIZE` has been declared to be 3.
- b) How many elements does the array contain?
- c) Use a `for` statement to initialize each element of the array to the sum of its indices. Assume that the integer variables `x` and `y` are declared as control variables.

**7.5** Find and correct the error in each of the following program segments:

- a) 

```
final int ARRAY_SIZE = 5;
ARRAY_SIZE = 10;
```
- b) Assume 

```
int[] b = new int[ 10 ];
for ( int i = 0; i <= b.length; i++ )
    b[ i ] = 1;
```
- c) Assume 

```
int[][] a = { { 1, 2 }, { 3, 4 } };
a[ 1, 1 ] = 5;
```

## Answers to Self-Review Exercises

**7.1** a) arrays. b) variables, type. c) enhanced `for` statement. d) index (or subscript or position number). e) two-dimensional. f) `for ( double d : numbers )`. g) an array of `Strings`, called `args` by convention. h) `args.length`. i) `test`. j) ellipsis (`...`).

- 7.2**
- a) False. An array can store only values of the same type.
  - b) False. An array index must be an integer or an integer expression.
  - c) For individual primitive-type elements of an array: False. A called method receives and manipulates a copy of the value of such an element, so modifications do not affect the original value. If the reference of an array is passed to a method, however, modifications to the array elements made in the called method are indeed reflected in the original. For individual elements of a reference type: True. A called method receives a copy of the reference of such an element, and changes to the referenced object will be reflected in the original array element.
  - d) False. Command-line arguments are separated by white space.

**7.3**

- a) 

```
final int ARRAY_SIZE = 10;
```
- b) 

```
double[] fractions = new double[ ARRAY_SIZE ];
```
- c) 

```
fractions[ 4 ]
```
- d) 

```
fractions[ 9 ] = 1.667;
```
- e) 

```
fractions[ 6 ] = 3.333;
```
- f) 

```
double total = 0.0;
for ( int x = 0; x < fractions.length; x++ )
    total += fractions[ x ];
```

**7.4**

- a) 

```
int[][] table = new int[ ARRAY_SIZE ][ ARRAY_SIZE ];
```
- b) Nine.
- c) 

```
for ( int x = 0; x < table.length; x++ )
    for ( int y = 0; y < table[ x ].length; y++ )
        table[ x ][ y ] = x + y;
```

- 7.5**
- a) Error: Assigning a value to a constant after it has been initialized. Correction: Assign the correct value to the constant in a `final int ARRAY_SIZE` declaration or declare another variable.
  - b) Error: Referencing an array element outside the bounds of the array (`b[10]`). Correction: Change the `<=` operator to `<`.
  - c) Error: Array indexing is performed incorrectly. Correction: Change the statement to `a[ 1 ][ 1 ] = 5;`.

## Exercises

- 7.6** Fill in the blanks in each of the following statements:
- One-dimensional array `p` contains four elements. The names of those elements are \_\_\_\_\_, \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - Naming an array, stating its type and specifying the number of dimensions in the array is called \_\_\_\_\_ the array.
  - In a two-dimensional array, the first index identifies the \_\_\_\_\_ of an element and the second index identifies the \_\_\_\_\_ of an element.
  - An  $m$ -by- $n$  array contains \_\_\_\_\_ rows, \_\_\_\_\_ columns and \_\_\_\_\_ elements.
  - The name of the element in row 3 and column 5 of array `d` is \_\_\_\_\_.
- 7.7** Determine whether each of the following is *true* or *false*. If *false*, explain why.
- To refer to a particular location or element within an array, we specify the name of the array and the value of the particular element.
  - An array declaration reserves space for the array.
  - To indicate that 100 locations should be reserved for integer array `p`, you write the declaration  

```
p[ 100 ];
```
  - An application that initializes the elements of a 15-element array to zero must contain at least one `for` statement.
  - An application that totals the elements of a two-dimensional array must contain nested `for` statements.
- 7.8** Write Java statements to accomplish each of the following tasks:
- Display the value of element 6 of array `f`.
  - Initialize each of the five elements of one-dimensional integer array `g` to 8.
  - Total the 100 elements of floating-point array `c`.
  - Copy 11-element array `a` into the first portion of array `b`, which contains 34 elements.
  - Determine and display the smallest and largest values contained in 99-element floating-point array `w`.
- 7.9** Consider a two-by-three integer array `t`.
- Write a statement that declares and creates `t`.
  - How many rows does `t` have?
  - How many columns does `t` have?
  - How many elements does `t` have?
  - Write access expressions for all the elements in row 1 of `t`.
  - Write access expressions for all the elements in column 2 of `t`.
  - Write a single statement that sets the element of `t` in row 0 and column 1 to zero.
  - Write individual statements to initialize each element of `t` to zero.
  - Write a nested `for` statement that initializes each element of `t` to zero.
  - Write a nested `for` statement that inputs the values for the elements of `t` from the user.
  - Write a series of statements that determines and displays the smallest value in `t`.
  - Write a single `printf` statement that displays the elements of the first row of `t`.
  - Write a statement that totals the elements of the third column of `t`. Do not use repetition.
  - Write a series of statements that displays the contents of `t` in tabular format. List the column indices as headings across the top, and list the row indices at the left of each row.
- 7.10** (*Sales Commissions*) Use a one-dimensional array to solve the following problem: A company pays its salespeople on a commission basis. The salespeople receive \$200 per week plus 9% of their gross sales for that week. For example, a salesperson who grosses \$5000 in sales in a week receives \$200 plus 9% of \$5000, or a total of \$650. Write an application (using an array of counters)

that determines how many of the salespeople earned salaries in each of the following ranges (assume that each salesperson's salary is truncated to an integer amount):

- a) \$200–299
- b) \$300–399
- c) \$400–499
- d) \$500–599
- e) \$600–699
- f) \$700–799
- g) \$800–899
- h) \$900–999
- i) \$1000 and over

Summarize the results in tabular format.

**7.11** Write statements that perform the following one-dimensional-array operations:

- a) Set the 10 elements of integer array `counts` to zero.
- b) Add one to each of the 15 elements of integer array `bonus`.
- c) Display the five values of integer array `bestScores` in column format.

**7.12** (*Duplicate Elimination*) Use a one-dimensional array to solve the following problem: Write an application that inputs five numbers, each between 10 and 100, inclusive. As each number is read, display it only if it's not a duplicate of a number already read. Provide for the “worst case,” in which all five numbers are different. Use the smallest possible array to solve this problem. Display the complete set of unique values input after the user enters each new value.

**7.13** Label the elements of three-by-five two-dimensional array `sales` to indicate the order in which they're set to zero by the following program segment:

```
for ( int row = 0; row < sales.length; row++ )
{
    for ( int col = 0; col < sales[ row ].length; col++ )
    {
        sales[ row ][ col ] = 0;
    }
}
```

**7.14** (*Variable-Length Argument List*) Write an application that calculates the product of a series of integers that are passed to method `product` using a variable-length argument list. Test your method with several calls, each with a different number of arguments.

**7.15** (*Command-Line Arguments*) Rewrite Fig. 7.2 so that the size of the array is specified by the first command-line argument. If no command-line argument is supplied, use 10 as the default size of the array.

**7.16** (*Using the Enhanced for Statement*) Write an application that uses an enhanced `for` statement to sum the `double` values passed by the command-line arguments. [*Hint: Use the static method `parseDouble` of class `Double` to convert a `String` to a `double` value.*]

**7.17** (*Dice Rolling*) Write an application to simulate the rolling of two dice. The application should use an object of class `Random` once to roll the first die and again to roll the second die. The sum of the two values should then be calculated. Each die can show an integer value from 1 to 6, so the sum of the values will vary from 2 to 12, with 7 being the most frequent sum, and 2 and 12 the least frequent. Figure 7.28 shows the 36 possible combinations of the two dice. Your application should roll the dice 36,000,000 times. Use a one-dimensional array to tally the number of times each possible sum appears. Display the results in tabular format.

|   | 1 | 2 | 3 | 4  | 5  | 6  |
|---|---|---|---|----|----|----|
| 1 | 2 | 3 | 4 | 5  | 6  | 7  |
| 2 | 3 | 4 | 5 | 6  | 7  | 8  |
| 3 | 4 | 5 | 6 | 7  | 8  | 9  |
| 4 | 5 | 6 | 7 | 8  | 9  | 10 |
| 5 | 6 | 7 | 8 | 9  | 10 | 11 |
| 6 | 7 | 8 | 9 | 10 | 11 | 12 |

**Fig. 7.28** | The 36 possible sums of two dice.

**7.18** (*Game of Craps*) Write an application that runs 1,000,000 games of craps (Fig. 6.8) and answers the following questions:

- How many games are won on the first roll, second roll, ..., twentieth roll and after the twentieth roll?
- How many games are lost on the first roll, second roll, ..., twentieth roll and after the twentieth roll?
- What are the chances of winning at craps? [*Note:* You should discover that craps is one of the fairest casino games. What do you suppose this means?]
- What is the average length of a game of craps?
- Do the chances of winning improve with the length of the game?

**7.19** (*Airline Reservations System*) A small airline has just purchased a computer for its new automated reservations system. You've been asked to develop the new system. You're to write an application to assign seats on each flight of the airline's only plane (capacity: 10 seats).

Your application should display the following alternatives: Please type 1 for First Class and Please type 2 for Economy. If the user types 1, your application should assign a seat in the first-class section (seats 1–5). If the user types 2, your application should assign a seat in the economy section (seats 6–10). Your application should then display a boarding pass indicating the person's seat number and whether it's in the first-class or economy section of the plane.

Use a one-dimensional array of primitive type `boolean` to represent the seating chart of the plane. Initialize all the elements of the array to `false` to indicate that all the seats are empty. As each seat is assigned, set the corresponding element of the array to `true` to indicate that the seat is no longer available.

Your application should never assign a seat that has already been assigned. When the economy section is full, your application should ask the person if it's acceptable to be placed in the first-class section (and vice versa). If yes, make the appropriate seat assignment. If no, display the message "Next flight leaves in 3 hours."

**7.20** (*Total Sales*) Use a two-dimensional array to solve the following problem: A company has four salespeople (1 to 4) who sell five different products (1 to 5). Once a day, each salesperson passes in a slip for each type of product sold. Each slip contains the following:

- The salesperson number
- The product number
- The total dollar value of that product sold that day

Thus, each salesperson passes in between 0 and 5 sales slips per day. Assume that the information from all the slips for last month is available. Write an application that will read all this information for last month's sales and summarize the total sales by salesperson and by product. All totals should be stored in the two-dimensional array `sales`. After processing all the information for last month, display the results in tabular format, with each column representing a salesperson and each row repre-

sending a particular product. Cross-total each row to get the total sales of each product for last month. Cross-total each column to get the total sales by salesperson for last month. Your output should include these cross-totals to the right of the totaled rows and to the bottom of the totaled columns.

**7.21 (Turtle Graphics)** The Logo language made the concept of *turtle graphics* famous. Imagine a mechanical turtle that walks around the room under the control of a Java application. The turtle holds a pen in one of two positions, up or down. While the pen is down, the turtle traces out shapes as it moves, and while the pen is up, the turtle moves about freely without writing anything. In this problem, you'll simulate the operation of the turtle and create a computerized sketchpad.

Use a 20-by-20 array `floor` that's initialized to zeros. Read commands from an array that contains them. Keep track of the current position of the turtle at all times and whether the pen is currently up or down. Assume that the turtle always starts at position (0, 0) of the floor with its pen up. The set of turtle commands your application must process are shown in Fig. 7.29.

| Command | Meaning                                                              |
|---------|----------------------------------------------------------------------|
| 1       | Pen up                                                               |
| 2       | Pen down                                                             |
| 3       | Turn right                                                           |
| 4       | Turn left                                                            |
| 5, 10   | Move forward 10 spaces (replace 10 for a different number of spaces) |
| 6       | Display the 20-by-20 array                                           |
| 9       | End of data (sentinel)                                               |

**Fig. 7.29** | Turtle graphics commands.

Suppose that the turtle is somewhere near the center of the floor. The following “program” would draw and display a 12-by-12 square, leaving the pen in the up position:

```

2
5, 12
3
5, 12
3
5, 12
3
5, 12
1
6
9

```

As the turtle moves with the pen down, set the appropriate elements of array `floor` to 1s. When the 6 command (display the array) is given, wherever there's a 1 in the array, display an asterisk or any character you choose. Wherever there's a 0, display a blank.

Write an application to implement the turtle graphics capabilities discussed here. Write several turtle graphics programs to draw interesting shapes. Add other commands to increase the power of your turtle graphics language.

**7.22 (Knight's Tour)** An interesting puzzler for chess buffs is the Knight's Tour problem, originally proposed by the mathematician Euler. Can the knight piece move around an empty chessboard and touch each of the 64 squares once and only once? We study this intriguing problem in depth here.

The knight makes only L-shaped moves (two spaces in one direction and one space in a perpendicular direction). Thus, as shown in Fig. 7.30, from a square near the middle of an empty chessboard, the knight (labeled K) can make eight different moves (numbered 0 through 7).

**Fig. 7.30** | The eight possible moves of the knight.

- Draw an eight-by-eight chessboard on a sheet of paper, and attempt a Knight's Tour by hand. Put a 1 in the starting square, a 2 in the second square, a 3 in the third, and so on. Before starting the tour, estimate how far you think you'll get, remembering that a full tour consists of 64 moves. How far did you get? Was this close to your estimate?
- Now let's develop an application that will move the knight around a chessboard. The board is represented by an eight-by-eight two-dimensional array `board`. Each square is initialized to zero. We describe each of the eight possible moves in terms of its horizontal and vertical components. For example, a move of type 0, as shown in Fig. 7.30, consists of moving two squares horizontally to the right and one square vertically upward. A move of type 2 consists of moving one square horizontally to the left and two squares vertically upward. Horizontal moves to the left and vertical moves upward are indicated with negative numbers. The eight moves may be described by two one-dimensional arrays, `horizontal` and `vertical`, as follows:

```
horizontal[ 0 ] = 2      vertical[ 0 ] = -1
horizontal[ 1 ] = 1      vertical[ 1 ] = -2
horizontal[ 2 ] = -1     vertical[ 2 ] = -2
horizontal[ 3 ] = -2     vertical[ 3 ] = -1
horizontal[ 4 ] = -2     vertical[ 4 ] = 1
horizontal[ 5 ] = -1     vertical[ 5 ] = 2
horizontal[ 6 ] = 1      vertical[ 6 ] = 2
horizontal[ 7 ] = 2      vertical[ 7 ] = 1
```

Let the variables `currentRow` and `currentColumn` indicate the row and column, respectively, of the knight's current position. To make a move of type `moveNumber`, where `moveNumber` is between 0 and 7, your application should use the statements

```
currentRow += vertical[ moveNumber ];
currentColumn += horizontal[ moveNumber ];
```

Write an application to move the knight around the chessboard. Keep a counter that varies from 1 to 64. Record the latest count in each square the knight moves to. Test each potential move to see if the knight has already visited that square. Test every potential move to ensure that the knight does not land off the chessboard. Run the application. How many moves did the knight make?

- c) After attempting to write and run a Knight's Tour application, you've probably developed some valuable insights. We'll use these insights to develop a *heuristic* (i.e., a common-sense rule) for moving the knight. Heuristics do not guarantee success, but a carefully developed heuristic greatly improves the chance of success. You may have observed that the outer squares are more troublesome than the squares nearer the center of the board. In fact, the most troublesome or inaccessible squares are the four corners.

Intuition may suggest that you should attempt to move the knight to the most troublesome squares first and leave open those that are easiest to get to, so that when the board gets congested near the end of the tour, there will be a greater chance of success.

We could develop an "accessibility heuristic" by classifying each of the squares according to how accessible it is and always moving the knight (using the knight's L-shaped moves) to the most inaccessible square. We label a two-dimensional array *accessibility* with numbers indicating from how many squares each particular square is accessible. On a blank chessboard, each of the 16 squares nearest the center is rated as 8, each corner square is rated as 2, and the other squares have accessibility numbers of 3, 4 or 6 as follows:

```

2 3 4 4 4 4 3 2
3 4 6 6 6 6 4 3
4 6 8 8 8 8 6 4
4 6 8 8 8 8 6 4
4 6 8 8 8 8 6 4
4 6 8 8 8 8 6 4
3 4 6 6 6 6 4 3
2 3 4 4 4 4 3 2

```

Write a new version of the Knight's Tour, using the accessibility heuristic. The knight should always move to the square with the lowest accessibility number. In case of a tie, the knight may move to any of the tied squares. Therefore, the tour may begin in any of the four corners. [Note: As the knight moves around the chessboard, your application should reduce the accessibility numbers as more squares become occupied. In this way, at any given time during the tour, each available square's accessibility number will remain equal to precisely the number of squares from which that square may be reached.] Run this version of your application. Did you get a full tour? Modify the application to run 64 tours, one starting from each square of the chessboard. How many full tours did you get?

- d) Write a version of the Knight's Tour application that, when encountering a tie between two or more squares, decides what square to choose by looking ahead to those squares reachable from the "tied" squares. Your application should move to the tied square for which the next move would arrive at a square with the lowest accessibility number.

**7.23** (*Knight's Tour: Brute-Force Approaches*) In part (c) of Exercise 7.22, we developed a solution to the Knight's Tour problem. The approach used, called the "accessibility heuristic," generates many solutions and executes efficiently.

As computers continue to increase in power, we'll be able to solve more problems with sheer computer power and relatively unsophisticated algorithms. Let's call this approach "brute-force" problem solving.

- a) Use random-number generation to enable the knight to walk around the chessboard (in its legitimate L-shaped moves) at random. Your application should run one tour and display the final chessboard. How far did the knight get?
- b) Most likely, the application in part (a) produced a relatively short tour. Now modify your application to attempt 1000 tours. Use a one-dimensional array to keep track of the number of tours of each length. When your application finishes attempting the 1000 tours, it should display this information in neat tabular format. What was the best result?

- c) Most likely, the application in part (b) gave you some “respectable” tours, but no full tours. Now let your application run until it produces a full tour. [*Caution:* This version of the application could run for hours on a powerful computer.] Once again, keep a table of the number of tours of each length, and display this table when the first full tour is found. How many tours did your application attempt before producing a full tour? How much time did it take?
- d) Compare the brute-force version of the Knight’s Tour with the accessibility-heuristic version. Which required a more careful study of the problem? Which algorithm was more difficult to develop? Which required more computer power? Could we be certain (in advance) of obtaining a full tour with the accessibility-heuristic approach? Could we be certain (in advance) of obtaining a full tour with the brute-force approach? Argue the pros and cons of brute-force problem solving in general.

**7.24** (*Eight Queens*) Another puzzler for chess buffs is the Eight Queens problem, which asks the following: Is it possible to place eight queens on an empty chessboard so that no queen is “attacking” any other (i.e., no two queens are in the same row, in the same column or along the same diagonal)? Use the thinking developed in Exercise 7.22 to formulate a heuristic for solving the Eight Queens problem. Run your application. [*Hint:* It’s possible to assign a value to each square of the chessboard to indicate how many squares of an empty chessboard are “eliminated” if a queen is placed in that square. Each of the corners would be assigned the value 22, as demonstrated by Fig. 7.31. Once these “elimination numbers” are placed in all 64 squares, an appropriate heuristic might be as follows: Place the next queen in the square with the smallest elimination number. Why is this strategy intuitively appealing?]

**Fig. 7.31** | The 22 squares eliminated by placing a queen in the upper left corner.

**7.25** (*Eight Queens: Brute-Force Approaches*) In this exercise, you’ll develop several brute-force approaches to solving the Eight Queens problem introduced in Exercise 7.24.

- Use the random brute-force technique developed in Exercise 7.23 to solve the Eight Queens problem.
- Use an exhaustive technique (i.e., try all possible combinations of eight queens on the chessboard) to solve the Eight Queens problem.
- Why might the exhaustive brute-force approach not be appropriate for solving the Knight’s Tour problem?
- Compare and contrast the random brute-force and exhaustive brute-force approaches.

**7.26** (*Knight’s Tour: Closed-Tour Test*) In the Knight’s Tour (Exercise 7.22), a full tour occurs when the knight makes 64 moves, touching each square of the chessboard once and only once. A closed tour occurs when the 64th move is one move away from the square in which the knight start-

ed the tour. Modify the application you wrote in Exercise 7.22 to test for a closed tour if a full tour has occurred.

**7.27** (*Sieve of Eratosthenes*) A prime number is any integer greater than 1 that's evenly divisible only by itself and 1. The Sieve of Eratosthenes is a method of finding prime numbers. It operates as follows:

- a) Create a primitive-type `boolean` array with all elements initialized to `true`. Array elements with prime indices will remain `true`. All other array elements will eventually be set to `false`.
- b) Starting with array index 2, determine whether a given element is `true`. If so, loop through the remainder of the array and set to `false` every element whose index is a multiple of the index for the element with value `true`. Then continue the process with the next element with value `true`. For array index 2, all elements beyond element 2 in the array that have indices which are multiples of 2 (indices 4, 6, 8, 10, etc.) will be set to `false`; for array index 3, all elements beyond element 3 in the array that have indices which are multiples of 3 (indices 6, 9, 12, 15, etc.) will be set to `false`; and so on.

When this process completes, the array elements that are still `true` indicate that the index is a prime number. These indices can be displayed. Write an application that uses an array of 1000 elements to determine and display the prime numbers between 2 and 999. Ignore array elements 0 and 1.

**7.28** (*Simulation: The Tortoise and the Hare*) In this problem, you'll re-create the classic race of the tortoise and the hare. You'll use random-number generation to develop a simulation of this memorable event.

Our contenders begin the race at square 1 of 70 squares. Each square represents a possible position along the race course. The finish line is at square 70. The first contender to reach or pass square 70 is rewarded with a pail of fresh carrots and lettuce. The course weaves its way up the side of a slippery mountain, so occasionally the contenders lose ground.

A clock ticks once per second. With each tick of the clock, your application should adjust the position of the animals according to the rules in Fig. 7.32. Use variables to keep track of the positions of the animals (i.e., position numbers are 1–70). Start each animal at position 1 (the “starting gate”). If an animal slips left before square 1, move it back to square 1.

| Animal   | Move type  | Percentage of the time | Actual move            |
|----------|------------|------------------------|------------------------|
| Tortoise | Fast plod  | 50%                    | 3 squares to the right |
|          | Slip       | 20%                    | 6 squares to the left  |
|          | Slow plod  | 30%                    | 1 square to the right  |
| Hare     | Sleep      | 20%                    | No move at all         |
|          | Big hop    | 20%                    | 9 squares to the right |
|          | Big slip   | 10%                    | 12 squares to the left |
|          | Small hop  | 30%                    | 1 square to the right  |
|          | Small slip | 20%                    | 2 squares to the left  |

**Fig. 7.32** | Rules for adjusting the positions of the tortoise and the hare.

Generate the percentages in Fig. 7.32 by producing a random integer  $i$  in the range  $1 \leq i \leq 10$ . For the tortoise, perform a “fast plod” when  $1 \leq i \leq 5$ , a “slip” when  $6 \leq i \leq 7$  or a “slow plod” when  $8 \leq i \leq 10$ . Use a similar technique to move the hare.

Begin the race by displaying

```
BANG !!!!!
AND THEY'RE OFF !!!!!
```

Then, for each tick of the clock (i.e., each repetition of a loop), display a 70-position line showing the letter T in the position of the tortoise and the letter H in the position of the hare. Occasionally, the contenders will land on the same square. In this case, the tortoise bites the hare, and your application should display OUCH!!! beginning at that position. All output positions other than the T, the H or the OUCH!!! (in case of a tie) should be blank.

After each line is displayed, test for whether either animal has reached or passed square 70. If so, display the winner and terminate the simulation. If the tortoise wins, display TORTOISE WINS!!! YAY!!! If the hare wins, display Hare wins. Yuch. If both animals win on the same tick of the clock, you may want to favor the tortoise (the “underdog”), or you may want to display It's a tie. If neither animal wins, perform the loop again to simulate the next tick of the clock. When you're ready to run your application, assemble a group of fans to watch the race. You'll be amazed at how involved your audience gets!

Later in the book, we introduce a number of Java capabilities, such as graphics, images, animation, sound and multithreading. As you study those features, you might enjoy enhancing your tortoise-and-hare contest simulation.

**7.29** (*Fibonacci Series*) The Fibonacci series

```
0, 1, 1, 2, 3, 5, 8, 13, 21, ...
```

begins with the terms 0 and 1 and has the property that each succeeding term is the sum of the two preceding terms.

- Write a method `fibonacci(n)` that calculates the  $n$ th Fibonacci number. Incorporate this method into an application that enables the user to enter the value of  $n$ .
- Determine the largest Fibonacci number that can be displayed on your system.
- Modify the application you wrote in part (a) to use `double` instead of `int` to calculate and return Fibonacci numbers, and use this modified application to repeat part (b).

*Exercises 7.30–7.33 are reasonably challenging. Once you've done them, you ought to be able to implement most popular card games easily.*

**7.30** (*Card Shuffling and Dealing*) Modify the application of Fig. 7.11 to deal a five-card poker hand. Then modify class `DeckOfCards` of Fig. 7.10 to include methods that determine whether a hand contains

- a pair
- two pairs
- three of a kind (e.g., three jacks)
- four of a kind (e.g., four aces)
- a flush (i.e., all five cards of the same suit)
- a straight (i.e., five cards of consecutive face values)
- a full house (i.e., two cards of one face value and three cards of another face value)

[Hint: Add methods `getFace` and `getSuit` to class `Card` of Fig. 7.9.]

**7.31** (*Card Shuffling and Dealing*) Use the methods developed in Exercise 7.30 to write an application that deals two five-card poker hands, evaluates each hand and determines which is better.

**7.32** (*Project: Card Shuffling and Dealing*) Modify the application developed in Exercise 7.31 so that it can simulate the dealer. The dealer's five-card hand is dealt “face down,” so the player cannot see it. The application should then evaluate the dealer's hand, and, based on the quality of the hand, the dealer should draw one, two or three more cards to replace the corresponding number of

unneeded cards in the original hand. The application should then reevaluate the dealer's hand. [*Caution:* This is a difficult problem!]

**7.33** (*Project: Card Shuffling and Dealing*) Modify the application developed in Exercise 7.32 so that it can handle the dealer's hand automatically, but the player is allowed to decide which cards of the player's hand to replace. The application should then evaluate both hands and determine who wins. Now use this new application to play 20 games against the computer. Who wins more games, you or the computer? Have a friend play 20 games against the computer. Who wins more games? Based on the results of these games, refine your poker-playing application. (This, too, is a difficult problem.) Play 20 more games. Does your modified application play a better game?

**7.34** (*Project: Card Shuffling and Dealing*) Modify the application of Figs. 7.9–7.11 to use `Face` and `Suit` enumerations to represent the faces and suits of the cards. Declare each of these enumerations as a `public` type in its own source-code file. Each `Card` should have a `Face` and a `Suit` instance variable. These should be initialized by the `Card` constructor. In class `DeckOfCards`, create an array of `Faces` that's initialized with the names of the constants in the `Face` enumeration and an array of `Suits` that's initialized with the names of the constants in the `Suit` enumeration. [*Note:* When you output an enumeration constant as a `String`, the name of the constant is displayed.]

## Special Section: Building Your Own Computer

In the next several problems, we take a temporary diversion from the world of high-level language programming to “peel open” a computer and look at its internal structure. We introduce machine-language programming and write several machine-language programs. To make this an especially valuable experience, we then build a computer (through the technique of software-based *simulation*) on which you can execute your machine-language programs.

**7.35** (*Machine-Language Programming*) Let's create a computer called the Simpletron. As its name implies, it's a simple, but powerful, machine. The Simpletron runs programs written in the only language it directly understands: Simpletron Machine Language (SML).

The Simpletron contains an *accumulator*—a special register in which information is put before the Simpletron uses that information in calculations or examines it in various ways. All the information in the Simpletron is handled in terms of *words*. A word is a signed four-digit decimal number, such as +3364, -1293, +0007 and -0001. The Simpletron is equipped with a 100-word memory, and these words are referenced by their location numbers 00, 01, ..., 99.

Before running an SML program, we must *load*, or place, the program into memory. The first instruction (or statement) of every SML program is always placed in location 00. The simulator will start executing at this location.

Each instruction written in SML occupies one word of the Simpletron's memory (and hence instructions are signed four-digit decimal numbers). We shall assume that the sign of an SML instruction is always plus, but the sign of a data word may be either plus or minus. Each location in the Simpletron's memory may contain an instruction, a data value used by a program or an unused (and hence undefined) area of memory. The first two digits of each SML instruction are the *operation code* specifying the operation to be performed. SML operation codes are summarized in Fig. 7.33.

| Operation code                    | Meaning                                                           |
|-----------------------------------|-------------------------------------------------------------------|
| <i>Input/output operations:</i>   |                                                                   |
| <code>final int READ = 10;</code> | Read a word from the keyboard into a specific location in memory. |

**Fig. 7.33** | Simpletron Machine Language (SML) operation codes. (Part I of 2.)

| Operation code                          | Meaning                                                                                                                    |
|-----------------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| <code>final int WRITE = 11;</code>      | Write a word from a specific location in memory to the screen.                                                             |
| <i>Load/store operations:</i>           |                                                                                                                            |
| <code>final int LOAD = 20;</code>       | Load a word from a specific location in memory into the accumulator.                                                       |
| <code>final int STORE = 21;</code>      | Store a word from the accumulator into a specific location in memory.                                                      |
| <i>Arithmetic operations:</i>           |                                                                                                                            |
| <code>final int ADD = 30;</code>        | Add a word from a specific location in memory to the word in the accumulator (leave the result in the accumulator).        |
| <code>final int SUBTRACT = 31;</code>   | Subtract a word from a specific location in memory from the word in the accumulator (leave the result in the accumulator). |
| <code>final int DIVIDE = 32;</code>     | Divide a word from a specific location in memory into the word in the accumulator (leave result in the accumulator).       |
| <code>final int MULTIPLY = 33;</code>   | Multiply a word from a specific location in memory by the word in the accumulator (leave the result in the accumulator).   |
| <i>Transfer-of-control operations:</i>  |                                                                                                                            |
| <code>final int BRANCH = 40;</code>     | Branch to a specific location in memory.                                                                                   |
| <code>final int BRANCHNEG = 41;</code>  | Branch to a specific location in memory if the accumulator is negative.                                                    |
| <code>final int BRANCHZERO = 42;</code> | Branch to a specific location in memory if the accumulator is zero.                                                        |
| <code>final int HALT = 43;</code>       | Halt. The program has completed its task.                                                                                  |

**Fig. 7.33** | Simpletron Machine Language (SML) operation codes. (Part 2 of 2.)

The last two digits of an SML instruction are the *operand*—the address of the memory location containing the word to which the operation applies. Let's consider several simple SML programs.

The first SML program (Fig. 7.34) reads two numbers from the keyboard and computes and displays their sum. The instruction `+1007` reads the first number from the keyboard and places it into location 07 (which has been initialized to 0). Then instruction `+1008` reads the next number into location 08. The *load* instruction, `+2007`, puts the first number into the accumulator, and the *add* instruction, `+3008`, adds the second number to the number in the accumulator. *All SML arithmetic instructions leave their results in the accumulator.* The *store* instruction, `+2109`, places the result back into memory location 09, from which the *write* instruction, `+1109`, takes the number and displays it (as a signed four-digit decimal number). The *halt* instruction, `+4300`, terminates execution.

The second SML program (Fig. 7.35) reads two numbers from the keyboard and determines and displays the larger value. Note the use of the instruction `+4107` as a conditional transfer of control, much the same as Java's *if* statement.

Now write SML programs to accomplish each of the following tasks:

- Use a sentinel-controlled loop to read 10 positive numbers. Compute and display their sum.

| Location | Number | Instruction  |
|----------|--------|--------------|
| 00       | +1007  | (Read A)     |
| 01       | +1008  | (Read B)     |
| 02       | +2007  | (Load A)     |
| 03       | +3008  | (Add B)      |
| 04       | +2109  | (Store C)    |
| 05       | +1109  | (Write C)    |
| 06       | +4300  | (Halt)       |
| 07       | +0000  | (Variable A) |
| 08       | +0000  | (Variable B) |
| 09       | +0000  | (Result C)   |

**Fig. 7.34** | SML program that reads two integers and computes their sum.

| Location | Number | Instruction             |
|----------|--------|-------------------------|
| 00       | +1009  | (Read A)                |
| 01       | +1010  | (Read B)                |
| 02       | +2009  | (Load A)                |
| 03       | +3110  | (Subtract B)            |
| 04       | +4107  | (Branch negative to 07) |
| 05       | +1109  | (Write A)               |
| 06       | +4300  | (Halt)                  |
| 07       | +1110  | (Write B)               |
| 08       | +4300  | (Halt)                  |
| 09       | +0000  | (Variable A)            |
| 10       | +0000  | (Variable B)            |

**Fig. 7.35** | SML program that reads two integers and determines the larger.

- b) Use a counter-controlled loop to read seven numbers, some positive and some negative, and compute and display their average.
- c) Read a series of numbers, and determine and display the largest number. The first number read indicates how many numbers should be processed.

**7.36 (Computer Simulator)** In this problem, you're going to build your own computer. No, you'll not be soldering components together. Rather, you'll use the powerful technique of *software-based simulation* to create an object-oriented *software model* of the Simpletron of Exercise 7.35. Your Simpletron simulator will turn the computer you're using into a Simpletron, and you'll actually be able to run, test and debug the SML programs you wrote in Exercise 7.35.

When you run your Simpletron simulator, it should begin by displaying:

```
*** Welcome to Simpletron! ***
*** Please enter your program one instruction ***
*** (or data word) at a time. I will display ***
*** the location number and a question mark (?) ***
```

```

*** You then type the word for that location.  ***
*** Type -99999 to stop entering your program.  ***

```

Your application should simulate the memory of the Simpletron with a one-dimensional array memory that has 100 elements. Now assume that the simulator is running, and let's examine the dialog as we enter the program of Fig. 7.35 (Exercise 7.35):

```

00 ? +1009
01 ? +1010
02 ? +2009
03 ? +3110
04 ? +4107
05 ? +1109
06 ? +4300
07 ? +1110
08 ? +4300
09 ? +0000
10 ? +0000
11 ? -99999

```

Your program should display the memory location followed by a question mark. Each value to the right of a question mark is input by the user. When the sentinel value -99999 is input, the program should display the following:

```

*** Program loading completed ***
*** Program execution begins ***

```

The SML program has now been placed (or loaded) in array memory. Now the Simpletron executes the SML program. Execution begins with the instruction in location 00 and, as in Java, continues sequentially, unless directed to some other part of the program by a transfer of control.

Use the variable `accumulator` to represent the accumulator register. Use the variable `instructionCounter` to keep track of the location in memory that contains the instruction being performed. Use the variable `operationCode` to indicate the operation currently being performed (i.e., the left two digits of the instruction word). Use the variable `operand` to indicate the memory location on which the current instruction operates. Thus, `operand` is the rightmost two digits of the instruction currently being performed. Do not execute instructions directly from memory. Rather, transfer the next instruction to be performed from memory to a variable called `instructionRegister`. Then “pick off” the left two digits and place them in `operationCode`, and “pick off” the right two digits and place them in `operand`. When the Simpletron begins execution, the special registers are all initialized to zero.

Now, let's “walk through” execution of the first SML instruction, +1009 in memory location 00. This procedure is called an *instruction-execution cycle*.

The `instructionCounter` tells us the location of the next instruction to be performed. We *fetch* the contents of that location from memory by using the Java statement

```
instructionRegister = memory[ instructionCounter ];
```

The operation code and the operand are extracted from the instruction register by the statements

```
operationCode = instructionRegister / 100;
operand = instructionRegister % 100;
```

Now the Simpletron must determine that the operation code is actually a *read* (versus a *write*, a *load*, and so on). A *switch* differentiates among the 12 operations of SML. In the *switch* statement, the behavior of various SML instructions is simulated as shown in Fig. 7.36. We discuss branch instructions shortly and leave the others to you.

When the SML program completes execution, the name and contents of each register as well as the complete contents of memory should be displayed. Such a printout is often called a computer dump (no, a computer dump is not a place where old computers go). To help you program your dump method, a sample dump format is shown in Fig. 7.37. A dump after executing a

| Instruction  | Description                                                                                             |
|--------------|---------------------------------------------------------------------------------------------------------|
| <i>read:</i> | Display the prompt "Enter an integer", then input the integer and store it in location memory[operand]. |
| <i>load:</i> | accumulator = memory[ operand ];                                                                        |
| <i>add:</i>  | accumulator += memory[ operand ];                                                                       |
| <i>halt:</i> | This instruction displays the message<br>*** Simpletron execution terminated ***                        |

**Fig. 7.36** | Behavior of several SML instructions in the Simpletron.

```

REGISTERS:

```

**Fig. 7.37** | A sample dump.

Simpletron program would show the actual values of instructions and data values at the moment execution terminated.

Let's proceed with the execution of our program's first instruction—namely, the +1009 in location 00. As we've indicated, the `switch` statement simulates this task by prompting the user to enter a value, reading the value and storing it in memory location `memory[ operand ]`. The value is then read into location 09.

At this point, simulation of the first instruction is completed. All that remains is to prepare the Simpletron to execute the next instruction. Since the instruction just performed was not a transfer of control, we need merely increment the instruction-counter register as follows:

```
instructionCounter++;
```

This action completes the simulated execution of the first instruction. The entire process (i.e., the instruction-execution cycle) begins anew with the fetch of the next instruction to execute.

Now let's consider how the branching instructions—the transfers of control—are simulated. All we need to do is adjust the value in the instruction counter appropriately. Therefore, the unconditional branch instruction (40) is simulated within the `switch` as

```
instructionCounter = operand;
```

The conditional "branch if accumulator is zero" instruction is simulated as

```
if ( accumulator == 0 )
    instructionCounter = operand;
```

At this point, you should implement your Simpletron simulator and run each of the SML programs you wrote in Exercise 7.35. If you desire, you may embellish SML with additional features and provide for these features in your simulator.

Your simulator should check for various types of errors. During the program-loading phase, for example, each number the user types into the Simpletron's memory must be in the range -9999 to +9999. Your simulator should test that each number entered is in this range and, if not, keep prompting the user to re-enter the number until the user enters a correct number.

During the execution phase, your simulator should check for various serious errors, such as attempts to divide by zero, attempts to execute invalid operation codes, and accumulator overflows (i.e., arithmetic operations resulting in values larger than +9999 or smaller than -9999). Such serious errors are called *fatal errors*. When a fatal error is detected, your simulator should display an error message, such as

```
*** Attempt to divide by zero ***
*** Simpletron execution abnormally terminated ***
```

and should display a full computer dump in the format we discussed previously. This treatment will help the user locate the error in the program.

**7.37 (Simpletron Simulator Modifications)** In Exercise 7.36, you wrote a software simulation of a computer that executes programs written in Simpletron Machine Language (SML). In this exercise, we propose several modifications and enhancements to the Simpletron Simulator. In the exercises of Chapter 22, we propose building a compiler that converts programs written in a high-level programming language (a variation of Basic) to Simpletron Machine Language. Some of the following modifications and enhancements may be required to execute the programs produced by the compiler:

- a) Extend the Simpletron Simulator's memory to contain 1000 memory locations to enable the Simpletron to handle larger programs.
- b) Allow the simulator to perform remainder calculations. This modification requires an additional SML instruction.
- c) Allow the simulator to perform exponentiation calculations. This modification requires an additional SML instruction.
- d) Modify the simulator to use hexadecimal rather than integer values to represent SML instructions.
- e) Modify the simulator to allow output of a newline. This modification requires an additional SML instruction.
- f) Modify the simulator to process floating-point values in addition to integer values.
- g) Modify the simulator to handle string input. [*Hint:* Each Simpletron word can be divided into two groups, each holding a two-digit integer. Each two-digit integer represents the ASCII (see Appendix B) decimal equivalent of a character. Add a machine-language instruction that will input a string and store the string, beginning at a specific Simpletron memory location. The first half of the word at that location will be a count of the number of characters in the string (i.e., the length of the string). Each succeeding half-word contains one ASCII character expressed as two decimal digits. The machine-language instruction converts each character into its ASCII equivalent and assigns it to a half-word.]
- h) Modify the simulator to handle output of strings stored in the format of part (g). [*Hint:* Add a machine-language instruction that will display a string, beginning at a certain Simpletron memory location. The first half of the word at that location is a count of the number of characters in the string (i.e., the length of the string). Each succeeding half-word contains one ASCII character expressed as two decimal digits. The machine-language instruction checks the length and displays the string by translating each two-digit number into its equivalent character.]

## Making a Difference

**7.38** (*Polling*) The Internet and the web are enabling more people to network, join a cause, voice opinions, and so on. The presidential candidates in 2008 used the Internet intensively to get out their messages and raise money for their campaigns. In this exercise, you'll write a simple polling program that allows users to rate five social-consciousness issues from 1 (least important) to 10 (most important). Pick five causes that are important to you (e.g., political issues, global environmental issues). Use a one-dimensional array `topics` (of type `String`) to store the five causes. To summarize the survey responses, use a 5-row, 10-column two-dimensional array `responses` (of type `int`), each row corresponding to an element in the `topics` array. When the program runs, it should ask the user to rate each issue. Have your friends and family respond to the survey. Then have the program display a summary of the results, including:

- a) A tabular report with the five topics down the left side and the 10 ratings across the top, listing in each column the number of ratings received for each topic.
- b) To the right of each row, show the average of the ratings for that issue.
- c) Which issue received the highest point total? Display both the issue and the point total.
- d) Which issue received the lowest point total? Display both the issue and the point total.

# Classes and Objects: A Deeper Look

*Instead of this absurd division  
into sexes, they ought to class  
people as static and dynamic.*

—Evelyn Waugh

*Is it a world to hide virtues in?*

—William Shakespeare

*But what, to serve  
our private ends,  
Forbids the cheating  
of our friends?*

—Charles Churchill

*This above all: to thine own self  
be true.*

—William Shakespeare

*Don't be "consistent," but be  
simply true.*

—Oliver Wendell Holmes, Jr.

## Objectives

In this chapter you'll learn:

- Encapsulation and data hiding.
- To use keyword `this`.
- To use `static` variables and methods.
- To import `static` members of a class.
- To use the `enum` type to create sets of constants with unique identifiers.
- To declare `enum` constants with parameters.
- To organize classes in packages to promote reuse.

- |                                                                                           |                                                                                 |

Summary | Self-Review Exercise | Answers to Self-Review Exercise | Exercises | Making a Difference

## 8.1 Introduction

We now take a deeper look at building classes, controlling access to members of a class and creating constructors. We discuss composition—a capability that allows a class to have references to objects of other classes as members. We reexamine the use of `set` and `get` methods. Recall that Section 6.10 introduced the basic `enum` type to declare a set of constants. In this chapter, we discuss the relationship between `enum` types and classes, demonstrating that an `enum`, like a class, can be declared in its own file with constructors, methods and fields. The chapter also discusses `static` class members and `final` instance variables in detail. Finally, we explain how to organize classes in packages to help manage large applications and promote reuse, then show a special relationship between classes in the same package.

## 8.2 Time Class Case Study

Our first example consists of two classes—`Time1` (Fig. 8.1) and `Time1Test` (Fig. 8.2). Class `Time1` represents the time of day. Class `Time1Test` is an application class in which the `main` method creates one object of class `Time1` and invokes its methods. These classes must be declared in *separate* files because they're both `public` classes. The output of this program appears in Fig. 8.2.

### *Time1 Class Declaration*

Class `Time1`'s `private int` instance variables `hour`, `minute` and `second` (Fig. 8.1, lines 6–8) represent the time in universal-time format (24-hour clock format in which hours are in the range 0–23). Class `Time1` contains `public` methods `setTime` (lines 12–25), `toUniversalString` (lines 28–31) and `toString` (lines 34–39). These methods are also called the **public services** or the **public interface** that the class provides to its clients.

### *Default Constructor*

In this example, class `Time1` does not declare a constructor, so the class has a default constructor that's supplied by the compiler. Each instance variable implicitly receives the

```

1 // Fig. 8.1: Time1.java
2 // Time1 class declaration maintains the time in 24-hour format.
3
4 public class Time1
5 {
6     private int hour; // 0 - 23
7     private int minute; // 0 - 59
8     private int second; // 0 - 59
9
10    // set a new time value using universal time; throw an
11    // exception if the hour, minute or second is invalid
12    public void setTime( int h, int m, int s )
13    {
14        // validate hour, minute and second
15        if ( ( h >= 0 && h < 24 ) && ( m >= 0 && m < 60 ) &&
16            ( s >= 0 && s < 60 ) )
17        {
18            hour = h;
19            minute = m;
20            second = s;
21        } // end if
22        else
23            throw new IllegalArgumentException(
24                "hour, minute and/or second was out of range" );
25    } // end method setTime
26
27    // convert to String in universal-time format (HH:MM:SS)
28    public String toUniversalString()
29    {
30        return String.format( "%02d:%02d:%02d", hour, minute, second );
31    } // end method toUniversalString
32
33    // convert to String in standard-time format (H:MM:SS AM or PM)
34    public String toString()
35    {
36        return String.format( "%d:%02d:%02d %s",
37            ( ( hour == 0 || hour == 12 ) ? 12 : hour % 12 ),
38            minute, second, ( hour < 12 ? "AM" : "PM" ) );
39    } // end method toString
40 } // end class Time1

```

**Fig. 8.1** | Time1 class declaration maintains the time in 24-hour format.

default value 0 for an `int`. Instance variables also can be initialized when they're declared in the class body, using the same initialization syntax as with a local variable.

### *Method setTime and Throwing Exceptions*

Method `setTime` (lines 12–25) is a `public` method that declares three `int` parameters and uses them to set the time. Lines 15–16 test each argument to determine whether the value is in the proper range, and, if so, lines 18–20 assign the values to the `hour`, `minute` and `second` instance variables. The `hour` value must be greater than or equal to 0 and less than 24, because universal-time format represents hours as integers from 0 to 23 (e.g., 1 PM is hour 13 and 11 PM is hour 23; midnight is hour 0 and noon is hour 12). Similarly, both

minute and second values must be greater than or equal to 0 and less than 60. For values outside these ranges, `setTime` throws an exception of type `IllegalArgumentException` (lines 23–24), which notifies the client code that an invalid argument was passed to the method. As you learned in Chapter 7, you can use `try...catch` to catch exceptions and attempt to recover from them, which we'll do in Fig. 8.2. The **throw statement** (line 23) creates a new object of type `IllegalArgumentException`. The parentheses following the class name indicate a call to the `IllegalArgumentException` constructor. In this case, we call the constructor that allows us to specify a custom error message. After the exception object is created, the `throw` statement immediately terminates method `setTime` and the exception is returned to the code that attempted to set the time.

### *Method toUniversalString*

Method `toUniversalString` (lines 28–31) takes no arguments and returns a `String` in universal-time format, consisting of two digits each for the hour, minute and second. For example, if the time were 1:30:07 PM, the method would return 13:30:07. Line 22 uses static method `format` of class `String` to return a `String` containing the formatted hour, minute and second values, each with two digits and possibly a leading 0 (specified with the 0 flag). Method `format` is similar to method `System.out.printf` except that `format` returns a formatted `String` rather than displaying it in a command window. The formatted `String` is returned by method `toUniversalString`.

### *Method toString*

Method `toString` (lines 34–39) takes no arguments and returns a `String` in standard-time format, consisting of the hour, minute and second values separated by colons and followed by AM or PM (e.g., 1:27:06 PM). Like method `toUniversalString`, method `toString` uses static `String` method `format` to format the minute and second as two-digit values, with leading zeros if necessary. Line 29 uses a conditional operator (`?:`) to determine the value for hour in the `String`—if the hour is 0 or 12 (AM or PM), it appears as 12; otherwise, it appears as a value from 1 to 11. The conditional operator in line 30 determines whether AM or PM will be returned as part of the `String`.

Recall from Section 6.4 that all objects in Java have a `toString` method that returns a `String` representation of the object. We chose to return a `String` containing the time in standard-time format. Method `toString` is called implicitly whenever a `Time1` object appears in the code where a `String` is needed, such as the value to output with a `%s` format specifier in a call to `System.out.printf`.

### *Using Class Time1*

As you learned in Chapter 3, each class you declare represents a new *type* in Java. Therefore, after declaring class `Time1`, we can use it as a type in declarations such as

```
Time1 sunset; // sunset can hold a reference to a Time1 object
```

The `Time1Test` application class (Fig. 8.2) uses class `Time1`. Line 9 declares and creates a `Time1` object and assigns it to local variable `time`. Operator `new` implicitly invokes class `Time1`'s default constructor, since `Time1` does not declare any constructors. Lines 12–16 output the time first in universal-time format (by invoking `time`'s `toUniversalString` method in line 13), then in standard-time format (by explicitly invoking `time`'s `toString` method in line 15) to confirm that the `Time1` object was initialized properly. Next, line 19

invokes method `setTime` of the `time` object to change the time. Then lines 20–24 output the time again in both formats to confirm that it was set correctly.

```

1 // Fig. 8.2: Time1Test.java
2 // Time1 object used in an application.
3
4 public class Time1Test
5 {
6     public static void main( String[] args )
7     {
8         // create and initialize a Time1 object
9         Time1 time = new Time1(); // invokes Time1 constructor
10
11        // output string representations of the time
12        System.out.print( "The initial universal time is: " );
13        System.out.println( time.toUniversalString() );
14        System.out.print( "The initial standard time is: " );
15        System.out.println( time.toString() );
16        System.out.println(); // output a blank line
17
18        // change time and output updated time
19        time.setTime( 13, 27, 6 );
20        System.out.print( "Universal time after setTime is: " );
21        System.out.println( time.toUniversalString() );
22        System.out.print( "Standard time after setTime is: " );
23        System.out.println( time.toString() );
24        System.out.println(); // output a blank line
25
26        // attempt to set time with invalid values
27        try
28        {
29            time.setTime( 99, 99, 99 ); // all values out of range
30        } // end try
31        catch ( IllegalArgumentException e )
32        {
33            System.out.printf( "Exception: %s\n\n", e.getMessage() );
34        } // end catch
35
36        // display time after attempt to set invalid values
37        System.out.println( "After attempting invalid settings:" );
38        System.out.print( "Universal time: " );
39        System.out.println( time.toUniversalString() );
40        System.out.print( "Standard time: " );
41        System.out.println( time.toString() );
42    } // end main
43 } // end class Time1Test

```

```

The initial universal time is: 00:00:00
The initial standard time is: 12:00:00 AM

Universal time after setTime is: 13:27:06
Standard time after setTime is: 1:27:06 PM

```

**Fig. 8.2** | Time1 object used in an application. (Part I of 2.)

```
Exception: hour, minute and/or second was out of range

After attempting invalid settings:
Universal time: 13:27:06
Standard time: 1:27:06 PM
```

**Fig. 8.2** | Time1 object used in an application. (Part 2 of 2.)

### *Calling Time1 Method setTime with Invalid Values*

To illustrate that method `setTime` validates its arguments, line 29 calls method `setTime` with invalid arguments of 99 for the hour, minute and second. This statement is placed in a try block (lines 27–30) in case `setTime` throws an `IllegalArgumentException`, which it will do since the arguments are all invalid. When this occurs, the exception is caught at lines 31–34, and line 33 displays the exception’s error message by calling its `getMessage` method. Lines 37–41 output the time again in both formats to confirm that `setTime` did not change the time when invalid arguments were supplied.

### *Notes on the Time1 Class Declaration*

Consider several issues of class design with respect to class `Time1`. The instance variables `hour`, `minute` and `second` are each declared `private`. The actual data representation used within the class is of no concern to the class’s clients. For example, it would be perfectly reasonable for `Time1` to represent the time internally as the number of seconds since midnight or the number of minutes and seconds since midnight. Clients could use the same `public` methods and get the same results without being aware of this. (Exercise 8.5 asks you to represent the time in class `Time1` as the number of seconds since midnight and show that indeed no change is visible to the clients of the class.)

### **Software Engineering Observation 8.1**

*Classes simplify programming, because the client can use only the `public` methods exposed by the class. Such methods are usually client oriented rather than implementation oriented. Clients are neither aware of, nor involved in, a class’s implementation. Clients generally care about what the class does but not how the class does it.*

### **Software Engineering Observation 8.2**

*Interfaces change less frequently than implementations. When an implementation changes, implementation-dependent code must change accordingly. Hiding the implementation reduces the possibility that other program parts will become dependent on class implementation details.*

## 8.3 Controlling Access to Members

The access modifiers `public` and `private` control access to a class’s variables and methods. In Chapter 9, we’ll introduce the additional access modifier `protected`. As we stated in Section 8.2, the primary purpose of `public` methods is to present to the class’s clients a view of the services the class provides (the class’s `public` interface). Clients need not be concerned with how the class accomplishes its tasks. For this reason, the class’s `private` variables and `private` methods (i.e., its implementation details) are *not* accessible to its clients.

Figure 8.3 demonstrates that private class members are not accessible outside the class. Lines 9–11 attempt to access directly the private instance variables `hour`, `minute` and `second` of the `Time1` object `time`. When this program is compiled, the compiler generates error messages that these private members are not accessible. This program assumes that the `Time1` class from Fig. 8.1 is used.

### Common Programming Error 8.1

*An attempt by a method that's not a member of a class to access a private member of that class is a compilation error.*

```

1 // Fig. 8.3: MemberAccessTest.java
2 // Private members of class Time1 are not accessible.
3 public class MemberAccessTest
4 {
5     public static void main( String[] args )
6     {
7         Time1 time = new Time1(); // create and initialize Time1 object
8
9         time.hour = 7; // error: hour has private access in Time1
10        time.minute = 15; // error: minute has private access in Time1
11        time.second = 30; // error: second has private access in Time1
12    } // end main
13 } // end class MemberAccessTest

```

```

MemberAccessTest.java:9: hour has private access in Time1
    time.hour = 7; // error: hour has private access in Time1
        ^
MemberAccessTest.java:10: minute has private access in Time1
    time.minute = 15; // error: minute has private access in Time1
        ^
MemberAccessTest.java:11: second has private access in Time1
    time.second = 30; // error: second has private access in Time1
        ^
3 errors

```

**Fig. 8.3** | Private members of class `Time1` are not accessible.

## 8.4 Referring to the Current Object's Members with the `this` Reference

Every object can access a reference to itself with keyword **this** (sometimes called the **this reference**). When a non-static method is called for a particular object, the method's body implicitly uses keyword `this` to refer to the object's instance variables and other methods. This enables the class's code to know which object should be manipulated. As you'll see in Fig. 8.4, you can also use keyword `this` explicitly in a non-static method's body. Section 8.5 shows another interesting use of keyword `this`. Section 8.11 explains why keyword `this` cannot be used in a static method.

We now demonstrate implicit and explicit use of the `this` reference (Fig. 8.4). This example is the first in which we declare *two* classes in one file—class `ThisTest` is declared

in lines 4–11, and class `SimpleTime` in lines 14–47. We do this to demonstrate that when you compile a `.java` file containing more than one class, the compiler produces a separate class file with the `.class` extension for every compiled class. In this case, two separate files are produced—`SimpleTime.class` and `ThisTest.class`. When one source-code (`.java`) file contains multiple class declarations, the compiler places both class files for those classes in the same directory. Note also in Fig. 8.4 that only class `ThisTest` is declared `public`. A source-code file can contain only one `public` class—otherwise, a compilation error occurs. Non-`public` classes can be used only by other classes in the same package. So, in this example, class `SimpleTime` can be used only by class `ThisTest`.

---

```

1 // Fig. 8.4: ThisTest.java
2 // this used implicitly and explicitly to refer to members of an object.
3
4 public class ThisTest
5 {
6     public static void main( String[] args )
7     {
8         SimpleTime time = new SimpleTime( 15, 30, 19 );
9         System.out.println( time.buildString() );
10    } // end main
11 } // end class ThisTest
12
13 // class SimpleTime demonstrates the "this" reference
14 class SimpleTime
15 {
16     private int hour; // 0-23
17     private int minute; // 0-59
18     private int second; // 0-59
19
20     // if the constructor uses parameter names identical to
21     // instance variable names the "this" reference is
22     // required to distinguish between the names
23     public SimpleTime( int hour, int minute, int second )
24     {
25         this.hour = hour; // set "this" object's hour
26         this.minute = minute; // set "this" object's minute
27         this.second = second; // set "this" object's second
28     } // end SimpleTime constructor
29
30     // use explicit and implicit "this" to call toUniversalString
31     public String buildString()
32     {
33         return String.format( "%24s: %s\n%24s: %s",
34             "this.toUniversalString()", this.toUniversalString(),
35             "toUniversalString()", toUniversalString() );
36     } // end method buildString
37
38     // convert to String in universal-time format (HH:MM:SS)
39     public String toUniversalString()
40     {

```

---

**Fig. 8.4** | `this` used implicitly and explicitly to refer to members of an object. (Part I of 2.)

```

41     // "this" is not required here to access instance variables,
42     // because method does not have local variables with same
43     // names as instance variables
44     return String.format( "%02d:%02d:%02d",
45         this.hour, this.minute, this.second );
46 } // end method toUniversalString
47 } // end class SimpleTime

```

```

this.toUniversalString(): 15:30:19
toUniversalString(): 15:30:19

```

**Fig. 8.4** | `this` used implicitly and explicitly to refer to members of an object. (Part 2 of 2.)

Class `SimpleTime` (lines 14–47) declares three private instance variables—`hour`, `minute` and `second` (lines 16–18). The constructor (lines 23–28) receives three `int` arguments to initialize a `SimpleTime` object. We used parameter names for the constructor (line 23) that are identical to the class's instance-variable names (lines 16–18). We don't recommend this practice, but we did it here to shadow (hide) the corresponding instance variables so that we could illustrate a case in which *explicit* use of the `this` reference is required. If a method contains a local variable with the *same* name as a field, that method will refer to the local variable rather than the field. In this case, the local variable shadows the field in the method's scope. However, the method can use the `this` reference to refer to the shadowed field explicitly, as shown on the left sides of the assignments in lines 25–27 for `SimpleTime`'s shadowed instance variables.

Method `buildString` (lines 31–36) returns a `String` created by a statement that uses the `this` reference explicitly and implicitly. Line 34 uses it explicitly to call method `toUniversalString`. Line 35 uses it implicitly to call the same method. Both lines perform the same task. You typically will not use `this` explicitly to reference other methods within the current object. Also, line 45 in method `toUniversalString` explicitly uses the `this` reference to access each instance variable. This is *not* necessary here, because the method does *not* have any local variables that shadow the instance variables of the class.

### Common Programming Error 8.2

*It's often a logic error when a method contains a parameter or local variable that has the same name as a field of the class. In this case, use reference `this` if you wish to access the field of the class—otherwise, the method parameter or local variable will be referenced.*

### Error-Prevention Tip 8.1

*Avoid method-parameter names or local-variable names that conflict with field names. This helps prevent subtle, hard-to-locate bugs.*

### Performance Tip 8.1

*Java conserves storage by maintaining only one copy of each method per class—this method is invoked by every object of the class. Each object, on the other hand, has its own copy of the class's instance variables (i.e., non-static fields). Each method of the class implicitly uses `this` to determine the specific object of the class to manipulate.*

Application class `ThisTest` (lines 4–11) demonstrates class `SimpleTime`. Line 8 creates an instance of class `SimpleTime` and invokes its constructor. Line 9 invokes the object's `buildString` method, then displays the results.

## 8.5 Time Class Case Study: Overloaded Constructors

As you know, you can declare your own constructor to specify how objects of a class should be initialized. Next, we demonstrate a class with several **overloaded constructors** that enable objects of that class to be initialized in different ways. To overload constructors, simply provide multiple constructor declarations with different signatures.

### *Class Time2 with Overloaded Constructors*

The default constructor for class `Time1` (Fig. 8.1) initialized `hour`, `minute` and `second` to their default 0 values (which is midnight in universal time). The default constructor does not enable the class's clients to initialize the time with specific nonzero values. Class `Time2` (Fig. 8.5) contains five overloaded constructors that provide convenient ways to initialize objects of the new class `Time2`. Each constructor initializes the object to begin in a consistent state. In this program, four of the constructors invoke a fifth, which in turn calls method `setTime` to ensure that the value supplied for `hour` is in the range 0 to 23, and the values for `minute` and `second` are each in the range 0 to 59. The compiler invokes the appropriate constructor by matching the number, types and order of the types of the arguments specified in the constructor call with the number, types and order of the types of the parameters specified in each constructor declaration. Class `Time2` also provides *set* and *get* methods for each instance variable.

---

```

1 // Fig. 8.5: Time2.java
2 // Time2 class declaration with overloaded constructors.
3
4 public class Time2
5 {
6     private int hour; // 0 - 23
7     private int minute; // 0 - 59
8     private int second; // 0 - 59
9
10    // Time2 no-argument constructor:
11    // initializes each instance variable to zero
12    public Time2()
13    {
14        this( 0, 0, 0 ); // invoke Time2 constructor with three arguments
15    } // end Time2 no-argument constructor
16
17    // Time2 constructor: hour supplied, minute and second defaulted to 0
18    public Time2( int h )
19    {
20        this( h, 0, 0 ); // invoke Time2 constructor with three arguments
21    } // end Time2 one-argument constructor
22

```

---

**Fig. 8.5** | Time2 class with overloaded constructors. (Part 1 of 3.)

```

23 // Time2 constructor: hour and minute supplied, second defaulted to 0
24 public Time2( int h, int m )
25 {
26     this( h, m, 0 ); // invoke Time2 constructor with three arguments
27 } // end Time2 two-argument constructor
28
29 // Time2 constructor: hour, minute and second supplied
30 public Time2( int h, int m, int s )
31 {
32     setTime( h, m, s ); // invoke setTime to validate time
33 } // end Time2 three-argument constructor
34
35 // Time2 constructor: another Time2 object supplied
36 public Time2( Time2 time )
37 {
38     // invoke Time2 three-argument constructor
39     this( time.getHour(), time.getMinute(), time.getSecond() );
40 } // end Time2 constructor with a Time2 object argument
41
42 // Set Methods
43 // set a new time value using universal time;
44 // validate the data
45 public void setTime( int h, int m, int s )
46 {
47     setHour( h ); // set the hour
48     setMinute( m ); // set the minute
49     setSecond( s ); // set the second
50 } // end method setTime
51
52 // validate and set hour
53 public void setHour( int h )
54 {
55     if ( h >= 0 && h < 24 )
56         hour = h;
57     else
58         throw new IllegalArgumentException( "hour must be 0-23" );
59 } // end method setHour
60
61 // validate and set minute
62 public void setMinute( int m )
63 {
64     if ( m >= 0 && m < 60 )
65         minute = m;
66     else
67         throw new IllegalArgumentException( "minute must be 0-59" );
68 } // end method setMinute
69
70 // validate and set second
71 public void setSecond( int s )
72 {
73     if ( s >= 0 && s < 60 )
74         second = ( ( s >= 0 && s < 60 ) ? s : 0 );

```

**Fig. 8.5** | Time2 class with overloaded constructors. (Part 2 of 3.)

```

75     else
76         throw new IllegalArgumentException( "second must be 0-59" );
77     } // end method setSecond
78
79     // Get Methods
80     // get hour value
81     public int getHour()
82     {
83         return hour;
84     } // end method getHour
85
86     // get minute value
87     public int getMinute()
88     {
89         return minute;
90     } // end method getMinute
91
92     // get second value
93     public int getSecond()
94     {
95         return second;
96     } // end method getSecond
97
98     // convert to String in universal-time format (HH:MM:SS)
99     public String toUniversalString()
100    {
101        return String.format(
102            "%02d:%02d:%02d", getHour(), getMinute(), getSecond() );
103    } // end method toUniversalString
104
105    // convert to String in standard-time format (H:MM:SS AM or PM)
106    public String toString()
107    {
108        return String.format( "%d:%02d:%02d %s",
109            ( getHour() == 0 || getHour() == 12 ) ? 12 : getHour() % 12 ),
110            getMinute(), getSecond(), ( getHour() < 12 ? "AM" : "PM" ) );
111    } // end method toString
112 } // end class Time2

```

**Fig. 8.5** | Time2 class with overloaded constructors. (Part 3 of 3.)

### *Class Time2's Constructors*

Lines 12–15 declare a so-called **no-argument constructor** that's invoked without arguments. Once you declare any constructors in a class, the compiler will *not* provide a default constructor. This no-argument constructor ensures that class Time2's clients can create Time2 objects with default values. Such a constructor simply initializes the object as specified in the constructor's body. In the body, we introduce a use of the `this` reference that's allowed only as the *first* statement in a constructor's body. Line 14 uses `this` in method-call syntax to invoke the Time2 constructor that takes three parameters (lines 30–33) with values of 0 for the hour, minute and second. Using the `this` reference as shown here is a popular way to reuse initialization code provided by another of the class's constructors rather than defining similar code in the no-argument constructor's body. We use this syn-

tax in four of the five `Time2` constructors to make the class easier to maintain and modify. If we need to change how objects of class `Time2` are initialized, only the constructor that the class's other constructors call will need to be modified. In fact, even that constructor might not need modification in this example. That constructor simply calls the `setTime` method to perform the actual initialization, so it's possible that the changes the class might require would be localized to the *set* methods.

### Common Programming Error 8.3

*It's a compilation error when `this` is used in a constructor's body to call another constructor of the same class if that call is not the first statement in the constructor. It's also a compilation error when a method attempts to invoke a constructor directly via `this`.*

### Common Programming Error 8.4

*A constructor can call methods of the class. Be aware that the instance variables might not yet be initialized, because the constructor is in the process of initializing the object. Using instance variables before they've been initialized properly is a logic error.*

Lines 18–21 declare a `Time2` constructor with a single `int` parameter representing the hour, which is passed with 0 for the minute and second to the constructor at lines 30–33. Lines 24–27 declare a `Time2` constructor that receives two `int` parameters representing the hour and minute, which are passed with 0 for the second to the constructor at lines 30–33. Like the no-argument constructor, each of these constructors invokes the constructor at lines 30–33 to minimize code duplication. Lines 30–33 declare the `Time2` constructor that receives three `int` parameters representing the hour, minute and second. This constructor calls `setTime` to initialize the instance variables.

Lines 36–40 declare a `Time2` constructor that receives a reference to another `Time2` object. In this case, the values from the `Time2` argument are passed to the three-argument constructor at lines 30–33 to initialize the hour, minute and second. Line 39 could have directly accessed the hour, minute and second values of the constructor's argument `time` with the expressions `time.hour`, `time.minute` and `time.second`—even though hour, minute and second are declared as `private` variables of class `Time2`. This is due to a special relationship between objects of the same class. We'll see in a moment why it's preferable to use the *get* methods.

### Software Engineering Observation 8.3

*When one object of a class has a reference to another object of the same class, the first object can access all the second object's data and methods (including those that are private).*

#### *Class `Time2`'s `setTime` Method*

Method `setTime` (lines 45–50) invokes the `setHour` (lines 53–59), `setMinute` (lines 62–68) and `setSecond` (lines 71–77) methods, which ensure that the value supplied for hour is in the range 0 to 23 and the values for minute and second are each in the range 0 to 59. If a value is out of range, each of these methods throws an `IllegalArgumentException` (lines 58, 67 and 76) indicating which value was out of range.

#### *Notes Regarding Class `Time2`'s `set` and `get` Methods and Constructors*

`Time2`'s *set* and *get* methods are called throughout the class. In particular, method `setTime` calls methods `setHour`, `setMinute` and `setSecond` in lines 47–49, and methods `toUni-`

versalString and toString call methods getHour, getMinute and getSecond in line 93 and lines 100–101, respectively. In each case, these methods could have accessed the class's private data directly without calling the *set* and *get* methods. However, consider changing the representation of the time from three int values (requiring 12 bytes of memory) to a single int value representing the total number of seconds that have elapsed since midnight (requiring only 4 bytes of memory). If we made such a change, only the bodies of the methods that access the private data directly would need to change—in particular, the individual *set* and *get* methods for the hour, minute and second. There would be no need to modify the bodies of methods setTime, toUniversalString or toString because they do not access the data directly. Designing the class in this manner reduces the likelihood of programming errors when altering the class's implementation.

Similarly, each Time2 constructor could include a copy of the appropriate statements from methods setHour, setMinute and setSecond. Doing so may be slightly more efficient, because the extra calls to the constructor and setTime are eliminated. However, *duplicating* statements in multiple methods or constructors makes changing the class's internal data representation more difficult. Having the Time2 constructors call the constructor with three arguments (or even call setTime directly) requires that any changes to the implementation of setTime be made only once. Also, the compiler can optimize programs by removing calls to simple methods and replacing them with the expanded code of their declarations—a technique known as **inlining the code**, which improves program performance.

#### Software Engineering Observation 8.4

*When implementing a method of a class, use the class's set and get methods to access the class's private data. This simplifies code maintenance and reduces the likelihood of errors.*

#### Using Class Time2's Overloaded Constructors

Class Time2Test (Fig. 8.6) invokes the overloaded Time2 constructors (lines 8–12 and 40). Line 8 invokes the no-argument constructor (Fig. 8.5, lines 12–15). Lines 9–13 of the program demonstrate passing arguments to the other Time2 constructors. Line 9 invokes the single-argument constructor that receives an int at lines 18–21 of Fig. 8.5. Line 10 invokes the two-argument constructor at lines 24–27 of Fig. 8.5. Line 11 invokes the three-argument constructor at lines 30–33 of Fig. 8.5. Line 12 invokes the single-argument constructor that takes a Time2 at lines 36–40 of Fig. 8.5. Next, the application displays the String representations of each Time2 object to confirm that it was initialized properly. Line 40 attempts to initialize t6 by creating a new Time2 object and passing three invalid values to the constructor. When the constructor attempts to use the invalid hour value to initialize the object's hour, an IllegalArgumentException occurs. We catch this exception at line 42 and display its error message, which results in the last line of the output.

```

    12:25:42 PM

Exception while initializing t6: hour must be 0-23

```

**Fig. 8.6** | Overloaded constructors used to initialize `Time2` objects. (Part 3 of 3.)

## 8.6 Default and No-Argument Constructors

Every class must have at least one constructor. If you do not provide any in a class's declaration, the compiler creates a default constructor that takes no arguments when it's invoked. The default constructor initializes the instance variables to the initial values specified in their declarations or to their default values (zero for primitive numeric types, `false` for boolean values and `null` for references). In Section 9.4.1, you'll learn that the default constructor performs another task also.

If your class declares constructors, the compiler will *not* create a default constructor. In this case, you must declare a no-argument constructor if default initialization is required. Like a default constructor, a no-argument constructor is invoked with empty parentheses. The `Time2` no-argument constructor (lines 12–15 of Fig. 8.5) explicitly initializes a `Time2` object by passing to the three-argument constructor 0 for each parameter. Since 0 is the default value for `int` instance variables, the no-argument constructor in this example could actually be declared with an empty body. In this case, each instance variable would receive its default value when the no-argument constructor was called. If we omit the no-argument constructor, clients of this class would not be able to create a `Time2` object with the expression `new Time2()`.

### Common Programming Error 8.5

*A compilation error occurs if a program attempts to initialize an object of a class by passing the wrong number or types of arguments to the class's constructor.*

### Error-Prevention Tip 8.2

*Ensure that you do not include a return type in a constructor definition. Java allows other methods of the class besides its constructors to have the same name as the class and to specify return types. Such methods are not constructors and will not be called when an object of the class is instantiated.*

## 8.7 Notes on Set and Get Methods

As you know, a class's private fields can be manipulated only by its methods. A typical manipulation might be the adjustment of a customer's bank balance (e.g., a private instance variable of a class `BankAccount`) by a method `computeInterest`. Classes often provide `public` methods to allow clients of the class to *set* (i.e., assign values to) or *get* (i.e., obtain the values of) private instance variables.

As a naming example, a method that sets instance variable `interestRate` would typically be named `setInterestRate` and a method that gets the `interestRate` would typically be called `getInterestRate`. *Set* methods are also commonly called **mutator methods**, because they typically change an object's state—i.e., modify the values of instance variables. *Get* methods are also commonly called **accessor methods** or **query methods**.

### Set and Get Methods vs. `public` Data

It would seem that providing *set* and *get* capabilities is essentially the same as making the instance variables `public`. This is one of the subtleties that makes Java so desirable for software engineering. A `public` instance variable can be read or written by any method that has a reference to an object containing that variable. If an instance variable is declared `private`, a `public` *get* method certainly allows other methods to access it, but the *get* method can *control* how the client can access it. For example, a *get* method might control the format of the data it returns and thus shield the client code from the actual data representation. A `public` *set* method can—and should—carefully scrutinize attempts to modify the variable's value and throw an exception if necessary. For example, an attempt to *set* the day of the month to 37 would be rejected, an attempt to *set* a person's weight to a negative value would be rejected, and so on. Thus, although *set* and *get* methods provide access to private data, the access is restricted by the implementation of the methods. This helps promote good software engineering.

### Validity Checking in Set Methods

The benefits of data integrity do not follow automatically simply because instance variables are declared `private`—you must provide validity checking. Java enables you to design better programs in a convenient manner. A class's *set* methods could return values indicating that attempts were made to assign invalid data to objects of the class. A client of the class could test the return value of a *set* method to determine whether the client's attempt to modify the object was successful and to take appropriate action. Typically, however, *set* methods have `void` return type and use exception handling to indicate attempts to assign invalid data. We discuss exception handling in detail in Chapter 11.

### Software Engineering Observation 8.5

*When appropriate, provide `public` methods to change and retrieve the values of private instance variables. This architecture helps hide the implementation of a class from its clients, which improves program modifiability.*

### Error-Prevention Tip 8.3

*Using *set* and *get* methods helps you create classes that are easier to debug and maintain. If only one method performs a particular task, such as setting the hour in a `Time2` object, it's easier to debug and maintain the class. If the hour is not being set properly, the code that actually modifies instance variable `hour` is localized to one method's body—`setHour`. Thus, your debugging efforts can be focused on method `setHour`.*

### Predicate Methods

Another common use for accessor methods is to test whether a condition is true or false—such methods are often called **predicate methods**. An example would be class `ArrayList`'s `isEmpty` method, which returns `true` if the `ArrayList` is empty. A program might test `isEmpty` before attempting to read another item from an `ArrayList`.

## 8.8 Composition

A class can have references to objects of other classes as members. This is called **composition** and is sometimes referred to as a *has-a relationship*. For example, an `AlarmClock` object needs to know the current time *and* the time when it's supposed to sound its alarm, so it's reasonable to include *two* references to `Time` objects in an `AlarmClock` object.

### Class Date

This composition example contains classes `Date` (Fig. 8.7), `Employee` (Fig. 8.8) and `EmployeeTest` (Fig. 8.9). Class `Date` (Fig. 8.7) declares instance variables `month`, `day` and `year` (lines 6–8) to represent a date. The constructor receives three `int` parameters. Line 17 invokes utility method `checkMonth` (lines 26–32) to validate the month—if the value is out-of-range the method throws an exception. Line 15 assumes that the value for `year` is correct and doesn't validate it. Line 19 invokes utility method `checkDay` (lines 35–48) to validate the day based on the current month and year. Line 38 determines whether the day is correct based on the number of days in the particular month. If the day is not correct, lines 42–43 determine whether the month is February, the day is 29 and the year is a leap year. If the day is still invalid, the method throws an exception. Lines 21–22 in the constructor output the `this` reference as a `String`. Since `this` is a reference to the current `Date` object, the object's `toString` method (lines 51–54) is called *implicitly* to obtain the object's `String` representation.

---

```

1 // Fig. 8.7: Date.java
2 // Date class declaration.
3
4 public class Date
5 {
6     private int month; // 1-12
7     private int day; // 1-31 based on month
8     private int year; // any year
9
10    private static final int[] daysPerMonth = // days in each month
11        { 0, 31, 28, 31, 30, 31, 30, 31, 31, 30, 31, 30, 31 };
12
13    // constructor: call checkMonth to confirm proper value for month;
14    // call checkDay to confirm proper value for day
15    public Date( int theMonth, int theDay, int theYear )
16    {
17        month = checkMonth( theMonth ); // validate month
18        year = theYear; // could validate year
19        day = checkDay( theDay ); // validate day
20
21        System.out.printf(
22            "Date object constructor for date %s\n", this );
23    } // end Date constructor
24
25    // utility method to confirm proper month value
26    private int checkMonth( int testMonth )
27    {
28        if ( testMonth > 0 && testMonth <= 12 ) // validate month
29            return testMonth;

```

---

**Fig. 8.7** | Date class declaration. (Part 1 of 2.)

```

30     else // month is invalid
31         throw new IllegalArgumentException( "month must be 1-12" );
32     } // end method checkMonth
33
34     // utility method to confirm proper day value based on month and year
35     private int checkDay( int testDay )
36     {
37         // check if day in range for month
38         if ( testDay > 0 && testDay <= daysPerMonth[ month ] )
39             return testDay;
40
41         // check for leap year
42         if ( month == 2 && testDay == 29 && ( year % 400 == 0 ||
43             ( year % 4 == 0 && year % 100 != 0 ) ) )
44             return testDay;
45
46         throw new IllegalArgumentException(
47             "day out-of-range for the specified month and year" );
48     } // end method checkDay
49
50     // return a String of the form month/day/year
51     public String toString()
52     {
53         return String.format( "%d/%d/%d", month, day, year );
54     } // end method toString
55 } // end class Date

```

**Fig. 8.7** | Date class declaration. (Part 2 of 2.)

### *Class Employee*

Class `Employee` (Fig. 8.8) has instance variables `firstName`, `lastName`, `birthDate` and `hireDate`. Members `firstName` and `lastName` (lines 6–7) are references to `String` objects. Members `birthDate` and `hireDate` (lines 8–9) are references to `Date` objects. This demonstrates that a class can have as instance variables references to objects of other classes. The `Employee` constructor (lines 12–19) takes four parameters—`first`, `last`, `dateOfBirth` and `dateOfHire`. The objects referenced by the parameters are assigned to the `Employee` object's instance variables. When class `Employee`'s `toString` method is called, it returns a `String` containing the employee's name and the `String` representations of the two `Date` objects. Each of these `Strings` is obtained with an *implicit* call to the `Date` class's `toString` method.

```

1 // Fig. 8.8: Employee.java
2 // Employee class with references to other objects.
3
4 public class Employee
5 {
6     private String firstName;
7     private String lastName;
8     private Date birthDate;
9     private Date hireDate;

```

**Fig. 8.8** | `Employee` class with references to other objects. (Part 1 of 2.)

```

10
11 // constructor to initialize name, birth date and hire date
12 public Employee( String first, String last, Date dateOfBirth,
13                 Date dateOfHire )
14 {
15     firstName = first;
16     lastName = last;
17     birthDate = dateOfBirth;
18     hireDate = dateOfHire;
19 } // end Employee constructor
20
21 // convert Employee to String format
22 public String toString()
23 {
24     return String.format( "%s, %s Hired: %s Birthday: %s",
25                           lastName, firstName, hireDate, birthDate );
26 } // end method toString
27 } // end class Employee

```

**Fig. 8.8** | Employee class with references to other objects. (Part 2 of 2.)

### *Class EmployeeTest*

Class `EmployeeTest` (Fig. 8.9) creates two `Date` objects (lines 8–9) to represent an `Employee`'s birthday and hire date, respectively. Line 10 creates an `Employee` and initializes its instance variables by passing to the constructor two `Strings` (representing the `Employee`'s first and last names) and two `Date` objects (representing the birthday and hire date). Line 12 implicitly invokes the `Employee`'s `toString` method to display the values of its instance variables and demonstrate that the object was initialized properly.

```

1 // Fig. 8.9: EmployeeTest.java
2 // Composition demonstration.
3
4 public class EmployeeTest
5 {
6     public static void main( String[] args )
7     {
8         Date birth = new Date( 7, 24, 1949 );
9         Date hire = new Date( 3, 12, 1988 );
10        Employee employee = new Employee( "Bob", "Blue", birth, hire );
11
12        System.out.println( employee );
13    } // end main
14 } // end class EmployeeTest

```

```

Date object constructor for date 7/24/1949
Date object constructor for date 3/12/1988
Blue, Bob Hired: 3/12/1988 Birthday: 7/24/1949

```

**Fig. 8.9** | Composition demonstration.

## 8.9 Enumerations

In Fig. 6.8, we introduced the basic enum type, which defines a set of constants represented as unique identifiers. In that program the enum constants represented the game's status. In this section we discuss the relationship between enum types and classes. Like classes, all enum types are reference types. An enum type is declared with an **enum declaration**, which is a comma-separated list of enum constants—the declaration may optionally include other components of traditional classes, such as constructors, fields and methods. Each enum declaration declares an enum class with the following restrictions:

1. enum constants are implicitly `final`, because they declare constants that shouldn't be modified.
2. enum constants are implicitly `static`.
3. Any attempt to create an object of an enum type with operator `new` results in a compilation error.

The enum constants can be used anywhere constants can be used, such as in the case labels of `switch` statements and to control enhanced `for` statements.

Figure 8.10 illustrates how to declare instance variables, a constructor and methods in an enum type. The enum declaration (lines 5–37) contains two parts—the enum constants and the other members of the enum type. The first part (lines 8–13) declares six enum constants. Each is optionally followed by arguments which are passed to the **enum constructor** (lines 20–24). Like the constructors you've seen in classes, an enum constructor can specify any number of parameters and can be overloaded. In this example, the enum constructor requires two `String` parameters. To properly initialize each enum constant, we follow it with parentheses containing two `String` arguments, which are passed to the enum's constructor. The second part (lines 16–36) declares the other members of the enum type—two instance variables (lines 16–17), a constructor (lines 20–24) and two methods (lines 27–30 and 33–36).

---

```

1 // Fig. 8.10: Book.java
2 // Declaring an enum type with constructor and explicit instance fields
3 // and accessors for these fields
4
5 public enum Book
6 {
7     // declare constants of enum type
8     JHTP( "Java How to Program", "2012" ),
9     CHTP( "C How to Program", "2007" ),
10    IW3HTP( "Internet & World Wide Web How to Program", "2008" ),
11    CPPHTP( "C++ How to Program", "2012" ),
12    VBHTP( "Visual Basic 2010 How to Program", "2011" ),
13    CSHARPHTP( "Visual C# 2010 How to Program", "2011" );
14
15    // instance fields
16    private final String title; // book title
17    private final String copyrightYear; // copyright year

```

---

**Fig. 8.10** | Declaring an enum type with constructor and explicit instance fields and accessors for these fields. (Part 1 of 2.)

```
18
19 // enum constructor
20 Book( String bookTitle, String year )
21 {
22     title = bookTitle;
23     copyrightYear = year;
24 } // end enum Book constructor
25
26 // accessor for field title
27 public String getTitle()
28 {
29     return title;
30 } // end method getTitle
31
32 // accessor for field copyrightYear
33 public String getCopyrightYear()
34 {
35     return copyrightYear;
36 } // end method getCopyrightYear
37 } // end enum Book
```

**Fig. 8.10** | Declaring an enum type with constructor and explicit instance fields and accessors for these fields. (Part 2 of 2.)

Lines 16–17 declare the instance variables `title` and `copyrightYear`. Each enum constant in `Book` is actually an object of type `Book` that has its own copy of instance variables `title` and `copyrightYear`. The constructor (lines 20–24) takes two `String` parameters, one that specifies the book’s title and one that specifies its copyright year. Lines 22–23 assign these parameters to the instance variables. Lines 27–36 declare two methods, which return the book title and copyright year, respectively.

Figure 8.11 tests the enum type `Book` and illustrates how to iterate through a range of enum constants. For every enum, the compiler generates the static method `values` (called in line 12) that returns an array of the enum’s constants in the order they were declared. Lines 12–14 use the enhanced `for` statement to display all the constants declared in the enum `Book`. Line 14 invokes the enum `Book`’s `getTitle` and `getCopyrightYear` methods to get the title and copyright year associated with the constant. When an enum constant is converted to a `String` (e.g., `book` in line 13), the constant’s identifier is used as the `String` representation (e.g., `JHTP` for the first enum constant).

```
1 // Fig. 8.11: EnumTest.java
2 // Testing enum type Book.
3 import java.util.EnumSet;
4
5 public class EnumTest
6 {
7     public static void main( String[] args )
8     {
9         System.out.println( "All books:\n" );
```

**Fig. 8.11** | Testing an enum type. (Part 1 of 2.)

```

10
11 // print all books in enum Book
12 for ( Book book : Book.values() )
13     System.out.printf( "%-10s%-45s%s\n", book,
14         book.getTitle(), book.getCopyrightYear() );
15
16 System.out.println( "\nDisplay a range of enum constants:\n" );
17
18 // print first four books
19 for ( Book book : EnumSet.range( Book.JHTP, Book.CPPHTP ) )
20     System.out.printf( "%-10s%-45s%s\n", book,
21         book.getTitle(), book.getCopyrightYear() );
22 } // end main
23 } // end class EnumTest

```

All books:

|           |                                          |      |
|-----------|------------------------------------------|------|
| JHTP      | Java How to Program                      | 2012 |
| CHTP      | C How to Program                         | 2007 |
| IW3HTP    | Internet & World Wide Web How to Program | 2008 |
| CPPHTP    | C++ How to Program                       | 2012 |
| VBHTP     | Visual Basic 2010 How to Program         | 2011 |
| CSHARPHTP | Visual C# 2010 How to Program            | 2011 |

Display a range of enum constants:

|        |                                          |      |
|--------|------------------------------------------|------|
| JHTP   | Java How to Program                      | 2012 |
| CHTP   | C How to Program                         | 2007 |
| IW3HTP | Internet & World Wide Web How to Program | 2008 |
| CPPHTP | C++ How to Program                       | 2012 |

**Fig. 8.11** | Testing an enum type. (Part 2 of 2.)

Lines 19–21 use the static method **range** of class **EnumSet** (declared in package `java.util`) to display a range of the enum `Book`'s constants. Method `range` takes two parameters—the first and the last enum constants in the range—and returns an `EnumSet` that contains all the constants between these two constants, inclusive. For example, the expression `EnumSet.range( Book.JHTP, Book.CPPHTP )` returns an `EnumSet` containing `Book.JHTP`, `Book.CHTP`, `Book.IW3HTP` and `Book.CPPHTP`. The enhanced `for` statement can be used with an `EnumSet` just as it can with an array, so lines 12–14 use it to display the title and copyright year of every book in the `EnumSet`. Class `EnumSet` provides several other static methods for creating sets of enum constants from the same enum type.

### Common Programming Error 8.6

*In an enum declaration, it's a syntax error to declare enum constants after the enum type's constructors, fields and methods.*

## 8.10 Garbage Collection and Method finalize

Every class in Java has the methods of class `Object` (package `java.lang`), one of which is the `finalize` method. This method is rarely used because it can cause performance problems and there's some uncertainty as to whether it will get called. Nevertheless, because

`finalize` is part of every class, we discuss it here to help you understand its intended purpose. The complete details of the `finalize` method are beyond the scope of this book, and most programmers should not use it—you'll soon see why. You'll learn more about class `Object` in Chapter 9.

Every object uses system resources, such as memory. We need a disciplined way to give resources back to the system when they're no longer needed; otherwise, "resource leaks" might occur that would prevent them from being reused by your program or possibly by other programs. The JVM performs automatic **garbage collection** to reclaim the memory occupied by objects that are no longer used. When there are no more references to an object, the object is eligible to be collected. This typically occurs when the JVM executes its **garbage collector**. So, memory leaks that are common in other languages like C and C++ (because memory is not automatically reclaimed in those languages) are less likely in Java, but some can still happen in subtle ways. Other types of resource leaks can occur. For example, an application may open a file on disk to modify its contents. If it does not close the file, the application must terminate before any other application can use it.

The **finalize method** is called by the garbage collector to perform **termination housekeeping** on an object just before the garbage collector reclaims the object's memory. Method `finalize` does not take parameters and has return type `void`. A problem with method `finalize` is that the garbage collector is not guaranteed to execute at a specified time. In fact, the garbage collector may never execute before a program terminates. Thus, it's unclear whether, or when, method `finalize` will be called. For this reason, most programmers should avoid method `finalize`.

### Software Engineering Observation 8.6

*A class that uses system resources, such as files on disk, should provide a method that programmers can call to release resources when they're no longer needed in a program. Many Java API classes provide `close` or `dispose` methods for this purpose. For example, class `Scanner` has a `close` method. We discuss new Java SE 7 features related to this in Section 11.13.*

## 8.11 static Class Members

Every object has its own copy of all the instance variables of the class. In certain cases, only one copy of a particular variable should be *shared* by all objects of a class. A **static field**—called a **class variable**—is used in such cases. A static variable represents **classwide information**—all objects of the class share the *same* piece of data. The declaration of a static variable begins with the keyword `static`.

Let's motivate static data with an example. Suppose that we have a video game with Martians and other space creatures. Each Martian tends to be brave and willing to attack other space creatures when the Martian is aware that at least four other Martians are present. If fewer than five Martians are present, each of them becomes cowardly. Thus, each Martian needs to know the `martianCount`. We could endow class `Martian` with `martianCount` as an instance variable. If we do this, then every Martian will have a *separate copy* of the instance variable, and every time we create a new Martian, we'll have to update the instance variable `martianCount` in every Martian object. This wastes space with the redundant copies, wastes time in updating the separate copies and is error prone. Instead, we declare `martianCount` to be `static`, making `martianCount` classwide data. Every Mar-

tian can see the `martianCount` as if it were an instance variable of class `Martian`, but only one copy of the static `martianCount` is maintained. This saves space. We save time by having the `Martian` constructor increment the static `martianCount`—there's only one copy, so we do not have to increment separate copies for each `Martian` object.

### Software Engineering Observation 8.7

*Use a static variable when all objects of a class must use the same copy of the variable.*

Static variables have class scope. We can access a class's public static members through a reference to any object of the class, or by qualifying the member name with the class name and a dot (`.`), as in `Math.random()`. A class's private static class members can be accessed by client code only through methods of the class. Actually, *static class members exist even when no objects of the class exist*—they're available as soon as the class is loaded into memory at execution time. To access a public static member when no objects of the class exist (and even when they do), prefix the class name and a dot (`.`) to the static member, as in `Math.PI`. To access a private static member when no objects of the class exist, provide a public static method and call it by qualifying its name with the class name and a dot.

### Software Engineering Observation 8.8

*Static class variables and methods exist, and can be used, even if no objects of that class have been instantiated.*

A static method cannot access non-static class members, because a static method can be called even when no objects of the class have been instantiated. For the same reason, the `this` reference cannot be used in a static method. The `this` reference must refer to a specific object of the class, and when a static method is called, there might not be any objects of its class in memory.

### Common Programming Error 8.7

*A compilation error occurs if a static method calls an instance (non-static) method in the same class by using only the method name. Similarly, a compilation error occurs if a static method attempts to access an instance variable in the same class by using only the variable name.*

### Common Programming Error 8.8

*Referring to `this` in a static method is a compilation error.*

## Tracking the Number of Employee Objects That Have Been Created

Our next program declares two classes—`Employee` (Fig. 8.12) and `EmployeeTest` (Fig. 8.13). Class `Employee` declares private static variable `count` (Fig. 8.12, line 9) and public static method `getCount` (lines 36–39). The static variable `count` is initialized to zero in line 9. If a static variable is not initialized, the compiler assigns it a default value—in this case 0, the default value for type `int`. Variable `count` maintains a count of the number of objects of class `Employee` that have been created so far.

When `Employee` objects exist, variable `count` can be used in any method of an `Employee` object—this example increments `count` in the constructor (line 18). The public

```

1 // Fig. 8.12: Employee.java
2 // Static variable used to maintain a count of the number of
3 // Employee objects in memory.
4
5 public class Employee
6 {
7     private String firstName;
8     private String lastName;
9     private static int count = 0; // number of Employees created
10
11     // initialize Employee, add 1 to static count and
12     // output String indicating that constructor was called
13     public Employee( String first, String last )
14     {
15         firstName = first;
16         lastName = last;
17
18         ++count; // increment static count of employees
19         System.out.printf( "Employee constructor: %s %s; count = %d\n",
20             firstName, lastName, count );
21     } // end Employee constructor
22
23     // get first name
24     public String getFirstName()
25     {
26         return firstName;
27     } // end method getFirstName
28
29     // get last name
30     public String getLastName()
31     {
32         return lastName;
33     } // end method getLastName
34
35     // static method to get static count value
36     public static int getCount()
37     {
38         return count;
39     } // end method getCount
40 } // end class Employee

```

**Fig. 8.12** | static variable used to maintain a count of the number of Employee objects in memory.

static method `getCount` (lines 36–39) returns the number of Employee objects that have been created so far. When no objects of class Employee exist, client code can access variable `count` by calling method `getCount` via the class name, as in `Employee.getCount()`. When objects exist, method `getCount` can also be called via any reference to an Employee object.

### Good Programming Practice 8.1

Invoke every static method by using the class name and a dot (.) to emphasize that the method being called is a static method.

EmployeeTest method main (Fig. 8.13) instantiates two Employee objects (lines 13–14). When each Employee object’s constructor is invoked, lines 15–16 of Fig. 8.12 assign the Employee’s first name and last name to instance variables firstName and lastName. These two statements do *not* make copies of the original String arguments. Actually, String objects in Java are **immutable**—they cannot be modified after they’re created. Therefore, it’s safe to have many references to one String object. This is not normally the case for objects of most other classes in Java. If String objects are immutable, you might wonder why we’re able to use operators + and += to concatenate String objects. String-concatenation operations actually result in a *new* Strings object containing the concatenated values. The original String objects are not modified.

When main has finished using the two Employee objects, the references e1 and e2 are set to null at lines 31–32. At this point, references e1 and e2 no longer refer to the objects that were instantiated in lines 13–14. The objects become “eligible for garbage collection” because there are no more references to them in the program.

---

```

1 // Fig. 8.13: EmployeeTest.java
2 // static member demonstration.
3
4 public class EmployeeTest
5 {
6     public static void main( String[] args )
7     {
8         // show that count is 0 before creating Employees
9         System.out.printf( "Employees before instantiation: %d\n",
10             Employee.getCount() );
11
12         // create two Employees; count should be 2
13         Employee e1 = new Employee( "Susan", "Baker" );
14         Employee e2 = new Employee( "Bob", "Blue" );
15
16         // show that count is 2 after creating two Employees
17         System.out.println( "\nEmployees after instantiation: " );
18         System.out.printf( "via e1.getCount(): %d\n", e1.getCount() );
19         System.out.printf( "via e2.getCount(): %d\n", e2.getCount() );
20         System.out.printf( "via Employee.getCount(): %d\n",
21             Employee.getCount() );
22
23         // get names of Employees
24         System.out.printf( "\nEmployee 1: %s %s\nEmployee 2: %s %s\n",
25             e1.getFirstName(), e1.getLastName(),
26             e2.getFirstName(), e2.getLastName() );
27
28         // in this example, there is only one reference to each Employee,
29         // so the following two statements indicate that these objects
30         // are eligible for garbage collection
31         e1 = null;
32         e2 = null;
33     } // end main
34 } // end class EmployeeTest

```

---

**Fig. 8.13** | static member demonstration. (Part I of 2.)

```

Employees before instantiation: 0
Employee constructor: Susan Baker; count = 1
Employee constructor: Bob Blue; count = 2

Employees after instantiation:
via e1.getCount(): 2
via e2.getCount(): 2
via Employee.getCount(): 2

Employee 1: Susan Baker
Employee 2: Bob Blue

```

**Fig. 8.13** | static member demonstration. (Part 2 of 2.)

Eventually, the garbage collector might reclaim the memory for these objects (or the operating system will reclaim the memory when the program terminates). The JVM does not guarantee when, or even whether, the garbage collector will execute. When it does, it's possible that no objects or only a subset of the eligible objects will be collected.

## 8.12 static Import

In Section 6.3, you learned about the `static` fields and methods of class `Math`. We invoked class `Math`'s `static` fields and methods by preceding each with the class name `Math` and a dot (`.`). A **static import** declaration enables you to import the `static` members of a class or interface so you can access them via their unqualified names in your class—the class name and a dot (`.`) are not required to use an imported `static` member.

A `static import` declaration has two forms—one that imports a particular `static` member (which is known as **single static import**) and one that imports *all* `static` members of a class (known as **static import on demand**). The following syntax imports a particular `static` member:

```
import static packageName.ClassName.staticMemberName;
```

where *packageName* is the package of the class (e.g., `java.lang`), *ClassName* is the name of the class (e.g., `Math`) and *staticMemberName* is the name of the `static` field or method (e.g., `PI` or `abs`). The following syntax imports all `static` members of a class:

```
import static packageName.ClassName.*;
```

The asterisk (`*`) indicates that *all* `static` members of the specified class should be available for use in the file. `static import` declarations import only `static` class members. Regular `import` statements should be used to specify the classes used in a program.

Figure 8.14 demonstrates a `static import`. Line 3 is a `static import` declaration, which imports all `static` fields and methods of class `Math` from package `java.lang`. Lines 9–12 access the `Math` class's `static` fields `E` (line 11) and `PI` (line 12) and the `static` methods `sqrt` (line 9) and `ceil` (line 10) without preceding the field names or method names with class name `Math` and a dot.

### Common Programming Error 8.9

A compilation error occurs if a program attempts to import two or more classes' `static` methods that have the same signature or `static` fields that have the same name.

```

1 // Fig. 8.14: StaticImportTest.java
2 // Static import of Math class methods.
3 import static java.lang.Math.*;
4
5 public class StaticImportTest
6 {
7     public static void main( String[] args )
8     {
9         System.out.printf( "sqrt( 900.0 ) = %.1f\n", sqrt( 900.0 ) );
10        System.out.printf( "ceil( -9.8 ) = %.1f\n", ceil( -9.8 ) );
11        System.out.printf( "E = %f\n", E );
12        System.out.printf( "PI = %f\n", PI );
13    } // end main
14 } // end class StaticImportTest

```

```

sqrt( 900.0 ) = 30.0
ceil( -9.8 ) = -9.0
log( E ) = 1.0
cos( 0.0 ) = 1.0

```

**Fig. 8.14** | Static import of Math class methods.

## 8.13 final Instance Variables

The **principle of least privilege** is fundamental to good software engineering. In the context of an application, it states that code should be granted only the amount of privilege and access that it needs to accomplish its designated task, but no more. This makes your programs more robust by preventing code from accidentally (or maliciously) modifying variable values and calling methods that should not be accessible.

Let's see how this principle applies to instance variables. Some of them need to be modifiable and some do not. You can use the keyword `final` to specify that a variable is not modifiable (i.e., it's a constant) and that any attempt to modify it is an error. For example,

```
private final int INCREMENT;
```

declares a `final` (constant) instance variable `INCREMENT` of type `int`. Such variables can be initialized when they're declared. If they are not, they *must* be initialized in every constructor of the class. Initializing constants in constructors enables each object of the class to have a different value for the constant. If a `final` variable is not initialized in its declaration or in every constructor, a compilation error occurs.

### Software Engineering Observation 8.9

Declaring an instance variable as `final` helps enforce the principle of least privilege. If an instance variable should not be modified, declare it to be `final` to prevent modification.

### Common Programming Error 8.10

Attempting to modify a `final` instance variable after it's initialized is a compilation error.

#### Error-Prevention Tip 8.4

Attempts to modify a `final` instance variable are caught at compilation time rather than causing execution-time errors. It's always preferable to get bugs out at compilation time, if possible, rather than allow them to slip through to execution time (where experience has found that repair is often many times more expensive).

#### Software Engineering Observation 8.10

A `final` field should also be declared `static` if it's initialized in its declaration to a value that's the same for all objects of the class. After this initialization, its value can never change. Therefore, we don't need a separate copy of the field for every object of the class. Making the field `static` enables all objects of the class to share the `final` field.

## 8.14 Time Class Case Study: Creating Packages

We've seen in almost every example in the text that classes from preexisting libraries, such as the Java API, can be imported into a Java program. Each class in the Java API belongs to a package that contains a group of related classes. These packages are defined once, but can be imported into many programs. As applications become more complex, packages help you manage the complexity of application components. Packages also facilitate software reuse by enabling programs to *import* classes from other packages (as we've done in most examples), rather than *copying* the classes into each program that uses them. Another benefit of packages is that they provide a convention for unique class names, which helps prevent class-name conflicts (discussed later in this section). This section introduces how to create your own packages.

### *Steps for Declaring a Reusable Class*

Before a class can be imported into multiple applications, it must be placed in a package to make it reusable. Figure 8.15 shows how to specify the package in which a class should be placed. Figure 8.16 shows how to import our packaged class so that it can be used in an application. The steps for creating a reusable class are:

1. Declare a `public` class. If the class is not `public`, it can be used only by other classes in the same package.
2. Choose a unique package name and add a **package declaration** to the source-code file for the reusable class declaration. In each Java source-code file there can be only one package declaration, and it must precede all other declarations and statements. Comments are not statements, so comments can be placed before a package statement in a file. [*Note:* If no package statement is provided, the class is placed in the so-called default package and is accessible only to other classes in the default package that are located in the same directory. All prior programs in this book having two or more classes have used this default package.]
3. Compile the class so that it's placed in the appropriate package directory.
4. Import the reusable class into a program and use the class.

We'll now discuss each of these steps in detail.

*Steps 1 and 2: Creating a public Class and Adding the package Statement*

For *Step 1*, we modify the public class `Time1` declared in Fig. 8.1. The new version is shown in Fig. 8.15. No modifications have been made to the implementation of the class, so we'll not discuss its implementation details again here.

For *Step 2*, we add a package declaration (line 3) that declares a package named `com.deitel.jhttp.ch08`. Placing a package declaration at the beginning of a Java source file indicates that the class declared in the file is part of the specified package. Only package declarations, import declarations and comments can appear outside the braces of a class declaration. A Java source-code file must have the following order:

---

```

1 // Fig. 8.15: Time1.java
2 // Time1 class declaration maintains the time in 24-hour format.
3 package com.deitel.jhttp.ch08;
4
5 public class Time1
6 {
7     private int hour; // 0 - 23
8     private int minute; // 0 - 59
9     private int second; // 0 - 59
10
11     // set a new time value using universal time; throw an
12     // exception if the hour, minute or second is invalid
13     public void setTime( int h, int m, int s )
14     {
15         // validate hour, minute and second
16         if ( ( h >= 0 && h < 24 ) && ( m >= 0 && m < 60 ) &&
17             ( s >= 0 && s < 60 ) )
18         {
19             hour = h;
20             minute = m;
21             second = s;
22         } // end if
23         else
24             throw new IllegalArgumentException(
25                 "hour, minute and/or second was out of range" );
26     } // end method setTime
27
28     // convert to String in universal-time format (HH:MM:SS)
29     public String toUniversalString()
30     {
31         return String.format( "%02d:%02d:%02d", hour, minute, second );
32     } // end method toUniversalString
33
34     // convert to String in standard-time format (H:MM:SS AM or PM)
35     public String toString()
36     {
37         return String.format( "%d:%02d:%02d %s",
38             ( ( hour == 0 || hour == 12 ) ? 12 : hour % 12 ),
39             minute, second, ( hour < 12 ? "AM" : "PM" ) );
40     } // end method toString
41 } // end class Time1

```

---

**Fig. 8.15** | Packaging class `Time1` for reuse.

1. a package declaration (if any),
2. import declarations (if any), then
3. class declarations.

Only one of the class declarations in a particular file can be `public`. Other classes in the file are placed in the package and can be used only by the other classes in the package. Non-`public` classes are in a package to support the reusable classes in the package.

To provide unique package names, start each one with your Internet domain name in reverse order. For example, our domain name is `deitel.com`, so our package names begin with `com.deitel`. For the domain name `yourcollege.edu`, the package name should begin with `edu.yourcollege`. After the domain name is reversed, you can choose any other names you want for your package. If you're part of a company with many divisions or a university with many schools, you may want to use the name of your division or school as the next name in the package. We chose to use `jhtp` as the next name in our package name to indicate that this class is from *Java How to Program*. The last name in our package name specifies that this package is for Chapter 8 (`ch08`).

### Step 3: Compiling the Packaged Class

Step 3 is to compile the class so that it's stored in the appropriate package. When a Java file containing a package declaration is compiled, the resulting class file is placed in the directory specified by the declaration. The package declaration in Fig. 8.15 indicates that class `Time1` should be placed in the directory

```
com
  deitel
    jhtp
      ch08
```

The names in the package declaration specify the exact location of the package's classes.

When compiling a class in a package, the `javac` command-line option `-d` causes the `javac` compiler to create appropriate directories based on the class's package declaration. The option also specifies where the directories should be stored. For example, in a command window, we used the compilation command

```
javac -d . Time1.java
```

to specify that the first directory in our package name should be placed in the current directory. The period (`.`) after `-d` in the preceding command represents the current directory on the Windows, UNIX, Linux and Mac OS X operating systems (and several others as well). After execution of the compilation command, the current directory contains a directory called `com`, `com` contains a directory called `deitel`, `deitel` contains a directory called `jhtp` and `jhtp` contains a directory called `ch08`. In the `ch08` directory, you can find the file `Time1.class`. [Note: If you do not use the `-d` option, then you must copy or move the class file to the appropriate package directory after compiling it.]

The package name is part of the **fully qualified class name**, so the name of class `Time1` is actually `com.deitel.jhtp.ch08.Time1`. You can use this fully qualified name in your programs, or you can `import` the class and use its **simple name** (the class name by itself—`Time1`) in the program. If another package also contains a `Time1` class, the fully qualified class names can be used to distinguish between the classes in the program and prevent a **name conflict** (also called a **name collision**).

*Step 4: Importing the Reusable Class*

Once it's compiled and stored in its package, the class can be imported into programs (*Step 4*). In the `Time1PackageTest` application of Fig. 8.16, line 3 specifies that class `Time1` should be imported for use in class `Time1PackageTest`. This class is in the default package because its `.java` file does not contain a package declaration. Since the two classes are in different packages, the `import` at line 3 is required so that class `Time1PackageTest` can use class `Time1`.

---

```

1 // Fig. 8.16: Time1PackageTest.java
2 // Time1 object used in an application.
3 import com.deitel.jhttp.ch08.Time1; // import class Time1
4
5 public class Time1PackageTest
6 {
7     public static void main( String[] args )
8     {
9         // create and initialize a Time1 object
10        Time1 time = new Time1(); // invokes Time1 constructor
11
12        // output string representations of the time
13        System.out.print( "The initial universal time is: " );
14        System.out.println( time.toUniversalString() );
15        System.out.print( "The initial standard time is: " );
16        System.out.println( time.toString() );
17        System.out.println(); // output a blank line
18
19        // change time and output updated time
20        time.setTime( 13, 27, 6 );
21        System.out.print( "Universal time after setTime is: " );
22        System.out.println( time.toUniversalString() );
23        System.out.print( "Standard time after setTime is: " );
24        System.out.println( time.toString() );
25        System.out.println(); // output a blank line
26
27        // attempt to set time with invalid values
28        try
29        {
30            time.setTime( 99, 99, 99 ); // all values out of range
31        } // end try
32        catch ( IllegalArgumentException e )
33        {
34            System.out.printf( "Exception: %s\n\n", e.getMessage() );
35        } // end catch
36
37        // display time after attempt to set invalid values
38        System.out.println( "After attempting invalid settings:" );
39        System.out.print( "Universal time: " );
40        System.out.println( time.toUniversalString() );
41        System.out.print( "Standard time: " );
42        System.out.println( time.toString() );
43    } // end main
44 } // end class Time1PackageTest

```

---

**Fig. 8.16** | Time1 object used in an application. (Part 1 of 2.)

```

The initial universal time is: 00:00:00
The initial standard time is: 12:00:00 AM

Universal time after setTime is: 13:27:06
Standard time after setTime is: 1:27:06 PM

Exception: hour, minute and/or second was out of range

After attempting invalid settings:
Universal time: 13:27:06
Standard time: 1:27:06 PM

```

**Fig. 8.16** | Time1 object used in an application. (Part 2 of 2.)

Line 3 is known as a **single-type-import declaration**—that is, the import declaration specifies one class to import. When your program uses multiple classes from the same package, you can import those classes with a single import declaration. For example, the import declaration

```
import java.util.*; // import classes from package java.util
```

uses an asterisk (\*) at its end to inform the compiler that all public classes from the `java.util` package are available for use in the program. This is known as a **type-import-on-demand declaration**. Only the classes from package `java.util` that are used in the program are loaded by the JVM. The preceding import allows you to use the simple name of any class from the `java.util` package in the program. Throughout this book, we use single-type-import declarations for clarity.

### Common Programming Error 8.11

*Using the import declaration `import java.*`; causes a compilation error. You must specify the exact name of the package from which you want to import classes.*

### Specifying the Classpath During Compilation

When compiling `Time1PackageTest`, `javac` must locate the `.class` file for `Time1` to ensure that class `Time1PackageTest` uses class `Time1` correctly. The compiler uses a special object called a **class loader** to locate the classes it needs. The class loader begins by searching the standard Java classes that are bundled with the JDK. Then it searches for **optional packages**. Java provides an **extension mechanism** that enables new (optional) packages to be added to Java for development and execution purposes. If the class is not found in the standard Java classes or in the extension classes, the class loader searches the **classpath**, which contains a list of locations in which classes are stored. The classpath consists of a list of directories or **archive files**, each separated by a **directory separator**—a semicolon (;) on Windows or a colon (:) on UNIX/Linux/Mac OS X. Archive files are individual files that contain directories of other files, typically in a compressed format. For example, the standard classes used by your programs are contained in the archive file `rt.jar`, which is installed with the JDK. Archive files normally end with the `.jar` or `.zip` file-name extensions. The directories and archive files specified in the classpath contain the classes you wish to make available to the Java compiler and the JVM.

By default, the classpath consists only of the current directory. However, the classpath can be modified by

1. providing the **-classpath** option to the javac compiler or
2. setting the **CLASSPATH environment variable** (a special variable that you define and the operating system maintains so that applications can search for classes in the specified locations).

For more information on the classpath, visit [download.oracle.com/javase/6/docs/technotes/tools/index.html#general](http://download.oracle.com/javase/6/docs/technotes/tools/index.html#general). The section entitled “General Information” contains information on setting the classpath for UNIX/Linux and Windows.

### Common Programming Error 8.12

*Specifying an explicit classpath eliminates the current directory from the classpath. This prevents classes in the current directory (including packages in the current directory) from loading properly. If classes must be loaded from the current directory, include a dot (.) in the classpath to specify the current directory.*

### Software Engineering Observation 8.11

*In general, it's a better practice to use the `-classpath` option of the compiler, rather than the CLASSPATH environment variable, to specify the classpath for a program. This enables each application to have its own classpath.*

### Error-Prevention Tip 8.5

*Specifying the classpath with the CLASSPATH environment variable can cause subtle and difficult-to-locate errors in programs that use different versions of the same package.*

For Figs. 8.15–8.16, we didn't specify an explicit classpath. Thus, to locate the classes in the `com.deitel.jhttp.ch08` package from this example, the class loader looks in the current directory for the first name in the package—`com`—then navigates the directory structure. Directory `com` contains the subdirectory `deitel`, `deitel` contains the subdirectory `jhttp`, and `jhttp` contains subdirectory `ch08`. In the `ch08` directory is the file `Time1.class`, which is loaded by the class loader to ensure that the class is used properly in our program.

### *Specifying the Classpath When Executing an Application*

When you execute an application, the JVM must be able to locate the `.class` files of the classes used in that application. Like the compiler, the `java` command uses a class loader that searches the standard classes and extension classes first, then searches the classpath (the current directory by default). The classpath can be specified explicitly by using either of the techniques discussed for the compiler. As with the compiler, it's better to specify an individual program's classpath via command-line JVM options. You can specify the classpath in the `java` command via the **-classpath** or **-cp** command-line options, followed by a list of directories or archive files separated by semicolons (;) on Microsoft Windows or by colons (:) on UNIX/Linux/Mac OS X. Again, if classes must be loaded from the current directory, be sure to include a dot (.) in the classpath to specify the current directory.

## 8.15 Package Access

If no access modifier (`public`, `protected` or `private`—we discuss `protected` in Chapter 9) is specified for a method or variable when it's declared in a class, the method or variable is considered to have **package access**. In a program that consists of one class

declaration, this has no specific effect. However, if a program uses multiple classes from the same package (i.e., a group of related classes), these classes can access each other's package-access members directly through references to objects of the appropriate classes, or in the case of static members through the class name. Package access is rarely used.

The application in Fig. 8.17 demonstrates package access. The application contains two classes in one source-code file—the `PackageDataTest` application class (lines 5–21) and the `PackageData` class (lines 24–41). When you compile this program, the compiler produces two separate `.class` files—`PackageDataTest.class` and `PackageData.class`. The compiler places the two `.class` files in the same directory, so the classes are considered to be part of the same package. Consequently, class `PackageDataTest` is allowed to modify the package-access data of `PackageData` objects. You can also place class `PackageData` (lines 24–41) in a separate source-code file. As long as both classes are compiled in the same directory on disk, the package-access relationship will still work.

---

```

1 // Fig. 8.17: PackageDataTest.java
2 // Package-access members of a class are accessible by other classes
3 // in the same package.
4
5 public class PackageDataTest
6 {
7     public static void main( String[] args )
8     {
9         PackageData packageData = new PackageData();
10
11         // output String representation of packageData
12         System.out.printf( "After instantiation:\n%s\n", packageData );
13
14         // change package access data in packageData object
15         packageData.number = 77;
16         packageData.string = "Goodbye";
17
18         // output String representation of packageData
19         System.out.printf( "\nAfter changing values:\n%s\n", packageData );
20     } // end main
21 } // end class PackageDataTest
22
23 // class with package access instance variables
24 class PackageData
25 {
26     int number; // package-access instance variable
27     String string; // package-access instance variable
28
29     // constructor
30     public PackageData()
31     {
32         number = 0;
33         string = "Hello";
34     } // end PackageData constructor
35

```

---

**Fig. 8.17** | Package-access members of a class are accessible by other classes in the same package. (Part I of 2.)

```

36 // return PackageData object String representation
37 public String toString()
38 {
39     return String.format( "number: %d; string: %s", number, string );
40 } // end method toString
41 } // end class PackageData

```

```

After instantiation:
number: 0; string: Hello

After changing values:
number: 77; string: Goodbye

```

**Fig. 8.17** | Package-access members of a class are accessible by other classes in the same package. (Part 2 of 2.)

In the `PackageData` class declaration, lines 26–27 declare the instance variables `number` and `string` with no access modifiers—therefore, these are package-access instance variables. The `PackageDataTest` application’s `main` method creates an instance of the `PackageData` class (line 9) to demonstrate the ability to modify the `PackageData` instance variables directly (as shown in lines 15–16). The results of the modification can be seen in the output window.

## 8.16 (Optional) GUI and Graphics Case Study: Using Objects with Graphics

Most of the graphics you’ve seen to this point did not vary with each program execution. Exercise 6.2 in Section 6.13 asked you to create a program that generated shapes and colors at random. In that exercise, the drawing changed every time the system called `paintComponent` to redraw the panel. To create a more consistent drawing that remains the same each time it’s drawn, we must store information about the displayed shapes so that we can reproduce them each time the system calls `paintComponent`. To do this, we’ll create a set of shape classes that store information about each shape. We’ll make these classes “smart” by allowing objects of these classes to draw themselves by using a `Graphics` object.

### *Class MyLine*

Figure 8.18 declares class `MyLine`, which has all these capabilities. Class `MyLine` imports `Color` and `Graphics` (lines 3–4). Lines 8–11 declare instance variables for the coordinates needed to draw a line, and line 12 declares the instance variable that stores the color of the line. The constructor at lines 15–22 takes five parameters, one for each instance variable that it initializes. Method `draw` at lines 25–29 requires a `Graphics` object and uses it to draw the line in the proper color and at the proper coordinates.

```

1 // Fig. 8.18: MyLine.java
2 // MyLine class represents a line.
3 import java.awt.Color;
4 import java.awt.Graphics;

```

**Fig. 8.18** | `MyLine` class represents a line. (Part 1 of 2.)

```

5
6 public class MyLine
7 {
8     private int x1; // x-coordinate of first endpoint
9     private int y1; // y-coordinate of first endpoint
10    private int x2; // x-coordinate of second endpoint
11    private int y2; // y-coordinate of second endpoint
12    private Color myColor; // color of this shape
13
14    // constructor with input values
15    public MyLine( int x1, int y1, int x2, int y2, Color color )
16    {
17        this.x1 = x1; // set x-coordinate of first endpoint
18        this.y1 = y1; // set y-coordinate of first endpoint
19        this.x2 = x2; // set x-coordinate of second endpoint
20        this.y2 = y2; // set y-coordinate of second endpoint
21        myColor = color; // set the color
22    } // end MyLine constructor
23
24    // Draw the line in the specified color
25    public void draw( Graphics g )
26    {
27        g.setColor( myColor );
28        g.drawLine( x1, y1, x2, y2 );
29    } // end method draw
30 } // end class MyLine

```

**Fig. 8.18** | MyLine class represents a line. (Part 2 of 2.)

### *Class DrawPanel*

In Fig. 8.19, we declare class `DrawPanel`, which will generate random objects of class `MyLine`. Line 12 declares a `MyLine` array to store the lines to draw. Inside the constructor (lines 15–37), line 17 sets the background color to `Color.WHITE`. Line 19 creates the array with a random length between 5 and 9. The loop at lines 22–36 creates a new `MyLine` for every element in the array. Lines 25–28 generate random coordinates for each line’s endpoints, and lines 31–32 generate a random color for the line. Line 35 creates a new `MyLine` object with the randomly generated values and stores it in the array.

Method `paintComponent` iterates through the `MyLine` objects in array `lines` using an enhanced `for` statement (lines 45–46). Each iteration calls the `draw` method of the current `MyLine` object and passes it the `Graphics` object for drawing on the panel.

```

1 // Fig. 8.19: DrawPanel.java
2 // Program that uses class MyLine
3 // to draw random lines.
4 import java.awt.Color;
5 import java.awt.Graphics;
6 import java.util.Random;
7 import javax.swing.JPanel;
8

```

**Fig. 8.19** | Creating random `MyLine` objects. (Part 1 of 2.)

```

9 public class DrawPanel extends JPanel
10 {
11     private Random randomNumbers = new Random();
12     private MyLine[] lines; // array of lines
13
14     // constructor, creates a panel with random shapes
15     public DrawPanel()
16     {
17         setBackground( Color.WHITE );
18
19         lines = new MyLine[ 5 + randomNumbers.nextInt( 5 ) ];
20
21         // create lines
22         for ( int count = 0; count < lines.length; count++ )
23         {
24             // generate random coordinates
25             int x1 = randomNumbers.nextInt( 300 );
26             int y1 = randomNumbers.nextInt( 300 );
27             int x2 = randomNumbers.nextInt( 300 );
28             int y2 = randomNumbers.nextInt( 300 );
29
30             // generate a random color
31             Color color = new Color( randomNumbers.nextInt( 256 ),
32                                     randomNumbers.nextInt( 256 ), randomNumbers.nextInt( 256 ) );
33
34             // add the line to the list of lines to be displayed
35             lines[ count ] = new MyLine( x1, y1, x2, y2, color );
36         } // end for
37     } // end DrawPanel constructor
38
39     // for each shape array, draw the individual shapes
40     public void paintComponent( Graphics g )
41     {
42         super.paintComponent( g );
43
44         // draw the lines
45         for ( MyLine line : lines )
46             line.draw( g );
47     } // end method paintComponent
48 } // end class DrawPanel

```

**Fig. 8.19** | Creating random MyLine objects. (Part 2 of 2.)

### *Class TestDraw*

Class TestDraw in Fig. 8.20 sets up a new window to display our drawing. Since we're setting the coordinates for the lines only once in the constructor, the drawing does not change if paintComponent is called to refresh the drawing on the screen.

```

1 // Fig. 8.20: TestDraw.java
2 // Creating a JFrame to display a DrawPanel.
3 import javax.swing.JFrame;

```

**Fig. 8.20** | Creating a JFrame to display a DrawPanel. (Part 1 of 2.)

```

4
5 public class TestDraw
6 {
7     public static void main( String[] args )
8     {
9         DrawPanel panel = new DrawPanel();
10        JFrame application = new JFrame();
11
12        application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
13        application.add( panel );
14        application.setSize( 300, 300 );
15        application.setVisible( true );
16    } // end main
17 } // end class TestDraw

```

**Fig. 8.20** | Creating a JFrame to display a DrawPanel. (Part 2 of 2.)

### *GUI and Graphics Case Study Exercise*

**8.1** Extend the program in Figs. 8.18–8.20 to randomly draw rectangles and ovals. Create classes `MyRectangle` and `MyOval`. Both of these classes should include  $x1$ ,  $y1$ ,  $x2$ ,  $y2$  coordinates, a color and a boolean flag to determine whether the shape is filled. Declare a constructor in each class with arguments for initializing all the instance variables. To help draw rectangles and ovals, each class should provide methods `getUpperLeftX`, `getUpperLeftY`, `getWidth` and `getHeight` that calculate the upper-left  $x$ -coordinate, upper-left  $y$ -coordinate, width and height, respectively. The upper-left  $x$ -coordinate is the smaller of the two  $x$ -coordinate values, the upper-left  $y$ -coordinate is the smaller of the two  $y$ -coordinate values, the width is the absolute value of the difference between the two  $x$ -coordinate values, and the height is the absolute value of the difference between the two  $y$ -coordinate values.

Class `DrawPanel`, which extends `JPanel` and handles the creation of the shapes, should declare three arrays, one for each shape type. The length of each array should be a random number between 1 and 5. The constructor of class `DrawPanel` will fill each array with shapes of random position, size, color and fill.

In addition, modify all three shape classes to include the following:

- A constructor with no arguments that sets the shape's coordinates to 0, the color of the shape to `Color.BLACK`, and the filled property to `false` (`MyRectangle` and `MyOval` only).
- Set* methods for the instance variables in each class. The methods that set a coordinate value should verify that the argument is greater than or equal to zero before setting the coordinate—if it's not, they should set the coordinate to zero. The constructor should call the *set* methods rather than initialize the local variables directly.

- c) *Get* methods for the instance variables in each class. Method draw should reference the coordinates by the *get* methods rather than access them directly.

## 8.17 Wrap-Up

In this chapter, we presented additional class concepts. The `Time` class case study presented a complete class declaration consisting of `private` data, overloaded `public` constructors for initialization flexibility, *set* and *get* methods for manipulating the class's data, and methods that returned `String` representations of a `Time` object in two different formats. You also learned that every class can declare a `toString` method that returns a `String` representation of an object of the class and that method `toString` can be called implicitly whenever an object of a class appears in the code where a `String` is expected.

You learned that the `this` reference is used implicitly in a class's non-static methods to access the class's instance variables and other non-static methods. You also saw explicit uses of the `this` reference to access the class's members (including shadowed fields) and how to use keyword `this` in a constructor to call another constructor of the class.

We discussed the differences between default constructors provided by the compiler and no-argument constructors provided by the programmer. You learned that a class can have references to objects of other classes as members—a concept known as composition. You saw the `enum` class type and learned how it can be used to create a set of constants for use in a program. You learned about Java's garbage-collection capability and how it (unpredictably) reclaims the memory of objects that are no longer used. The chapter explained the motivation for `static` fields in a class and demonstrated how to declare and use `static` fields and methods in your own classes. You also learned how to declare and initialize `final` variables.

You learned how to package your own classes for reuse and how to import those classes into an application. Finally, you learned that fields declared without an access modifier are given package access by default. You saw the relationship between classes in the same package that allows each class in a package to access the package-access members of other classes in the package.

In the next chapter, you'll learn about an important aspect of object-oriented programming in Java—inheritance. You'll see that all classes in Java are related directly or indirectly to the class called `Object`. You'll also begin to understand how the relationships between classes enable you to build more powerful applications.

## Summary

### Section 8.2 Time Class Case Study

- The `public` methods of a class are also known as the class's `public` services or `public` interface (p. 312). They present to the class's clients a view of the services the class provides.
- A class's `private` members are not accessible to its clients.
- `String` class `static` method `format` (p. 314) is similar to method `System.out.printf` except that `format` returns a formatted `String` rather than displaying it in a command window.
- All objects in Java have a `toString` method that returns a `String` representation of the object. Method `toString` is called implicitly when an object appears in code where a `String` is needed.

### Section 8.3 Controlling Access to Members

- The access modifiers `public` and `private` control access to a class's variables and methods.

- The primary purpose of `public` methods is to present to the class's clients a view of the services the class provides. Clients need not be concerned with how the class accomplishes its tasks.
- A class's private variables and private methods (i.e., its implementation details) are not accessible to its clients.

#### *Section 8.4 Referring to the Current Object's Members with the `this` Reference*

- A non-static method of an object implicitly uses keyword `this` (p. 317) to refer to the object's instance variables and other methods. Keyword `this` can also be used explicitly.
- The compiler produces a separate file with the `.class` extension for every compiled class.
- If a local variable has the same name as a class's field, the local variable shadows the field. You can use the `this` reference in a method to refer to the shadowed field explicitly.

#### *Section 8.5 Time Class Case Study: Overloaded Constructors*

- Overloaded constructors enable objects of a class to be initialized in different ways. The compiler differentiates overloaded constructors (p. 320) by their signatures.
- To call one constructor of a class from another of the same class, you can use the `this` keyword followed by parentheses containing the constructor arguments. Such a constructor call must appear as the first statement in the constructor's body.

#### *Section 8.6 Default and No-Argument Constructors*

- If no constructors are provided in a class, the compiler creates a default constructor.
- If a class declares constructors, the compiler will not create a default constructor. In this case, you must declare a no-argument constructor (p. 322) if default initialization is required.

#### *Section 8.7 Notes on Set and Get Methods*

- *Set* methods are commonly called mutator methods (p. 327) because they typically change a value. *Get* methods are commonly called accessor methods (p. 327) or query methods. A predicate method (p. 327) tests whether a condition is true or false.

#### *Section 8.8 Composition*

- A class can have references to objects of other classes as members. This is called composition (p. 328) and is sometimes referred to as a *has-a* relationship.

#### *Section 8.9 Enumerations*

- All `enum` types (p. 331) are reference types. An `enum` type is declared with an `enum` declaration, which is a comma-separated list of `enum` constants. The declaration may optionally include other components of traditional classes, such as constructors, fields and methods.
- `enum` constants are implicitly `final`, because they declare constants that should not be modified.
- `enum` constants are implicitly `static`.
- Any attempt to create an object of an `enum` type with operator `new` results in a compilation error.
- `enum` constants can be used anywhere constants can be used, such as in the case labels of `switch` statements and to control enhanced `for` statements.
- Each `enum` constant in an `enum` declaration is optionally followed by arguments which are passed to the `enum` constructor.
- For every `enum`, the compiler generates a `static` method called `values` (p. 332) that returns an array of the `enum`'s constants in the order in which they were declared.
- `EnumSet` `static` method `range` (p. 333) receives the first and last `enum` constants in a range and returns an `EnumSet` that contains all the constants between these two constants, inclusive.

### *Section 8.10 Garbage Collection and Method finalize*

- Every class in Java has the methods of class `Object`, one of which is the `finalize` method.
- The Java Virtual Machine (JVM) performs automatic garbage collection (p. 334) to reclaim the memory occupied by objects that are no longer in use. When there are no more references to an object, the object is eligible for garbage collection. The memory for such an object can be reclaimed when the JVM executes its garbage collector.
- The `finalize` method (p. 334) is called by the garbage collector just before it reclaims the object's memory. Method `finalize` does not take parameters and has return type `void`.
- The garbage collector (p. 334) may never execute before a program terminates. Thus, it's unclear whether, or when, method `finalize` will be called.

### *Section 8.11 static Class Members*

- A `static` variable (p. 334) represents classwide information that's shared among the class's objects.
- Static variables have class scope. A class's `public static` members can be accessed through a reference to any object of the class, or they can be accessed by qualifying the member name with the class name and a dot (`.`). Client code can access a class's `private static` class members only through methods of the class.
- `static` class members exist as soon as the class is loaded into memory.
- A method declared `static` cannot access non-`static` class members, because a `static` method can be called even when no objects of the class have been instantiated.
- The `this` reference cannot be used in a `static` method.

### *Section 8.12 static Import*

- A `static import` declaration (p. 338) enables you to refer to imported `static` members without the class name and a dot (`.`). A single `static import` declaration imports one `static` member, and a `static import on demand` imports all `static` members of a class.

### *Section 8.13 final Instance Variables*

- In the context of an application, the principle of least privilege (p. 339) states that code should be granted only the amount of privilege and access that it needs to accomplish its designated task.
- Keyword `final` specifies that a variable is not modifiable. Such variables must be initialized when they're declared or by each of a class's constructors.

### *Section 8.14 Time Class Case Study: Creating Packages*

- Each class in the Java API belongs to a package that contains a group of related classes. Packages help manage the complexity of application components and facilitate software reuse.
- Packages provide a convention for unique class names that helps prevent class-name conflicts (p. 342).
- Before a class can be imported into multiple applications, it must be placed in a package. There can be only one package declaration (p. 340) in each Java source-code file, and it must precede all other declarations and statements in the file.
- Every package name should start with your Internet domain name in reverse order. After the domain name is reversed, you can choose any other names you want for your package.
- When compiling a class in a package, the `javac` command-line option `-d` (p. 342) specifies where to store the package and causes the compiler to create the package's directories if they do not exist.
- The package name is part of the fully qualified class name (p. 342). This helps prevent name conflicts.

- A single-type-import declaration (p. 344) specifies one class to import. A type-import-on-demand declaration (p. 344) imports only the classes that the program uses from a particular package.
- The compiler uses a class loader (p. 344) to locate the classes it needs in the classpath. The classpath consists of a list of directories or archive files, each separated by a directory separator (p. 344).
- The classpath for the compiler and JVM can be specified by providing the `-classpath` option (p. 345) to the `javac` or `java` command, or by setting the `CLASSPATH` environment variable. If classes must be loaded from the current directory, include a dot (`.`) in the classpath.

### Section 8.15 Package Access

- If no access modifier is specified for a method or variable when it's declared in a class, the method or variable is considered to have package access (p. 345).

## Self-Review Exercise

**8.1** Fill in the blanks in each of the following statements:

- When compiling a class in a package, the `javac` command-line option \_\_\_\_\_ specifies where to store the package and causes the compiler to create the package's directories if they do not exist.
- `String` class static method \_\_\_\_\_ is similar to method `System.out.printf`, but returns a formatted `String` rather than displaying a `String` in a command window.
- If a method contains a local variable with the same name as one of its class's fields, the local variable \_\_\_\_\_ the field in that method's scope.
- The \_\_\_\_\_ method is called by the garbage collector just before it reclaims an object's memory.
- A(n) \_\_\_\_\_ declaration specifies one class to import.
- If a class declares constructors, the compiler will not create a(n) \_\_\_\_\_.
- An object's \_\_\_\_\_ method is called implicitly when an object appears in code where a `String` is needed.
- `Get` methods are commonly called \_\_\_\_\_ or \_\_\_\_\_.
- A(n) \_\_\_\_\_ method tests whether a condition is true or false.
- For every enum, the compiler generates a static method called \_\_\_\_\_ that returns an array of the enum's constants in the order in which they were declared.
- Composition is sometimes referred to as a(n) \_\_\_\_\_ relationship.
- A(n) \_\_\_\_\_ declaration contains a comma-separated list of constants.
- A(n) \_\_\_\_\_ variable represents classwide information that's shared by all the objects of the class.
- A(n) \_\_\_\_\_ declaration imports one static member.
- The \_\_\_\_\_ states that code should be granted only the amount of privilege and access that it needs to accomplish its designated task.
- Keyword \_\_\_\_\_ specifies that a variable is not modifiable.
- There can be only one \_\_\_\_\_ in a Java source-code file, and it must precede all other declarations and statements in the file.
- A(n) \_\_\_\_\_ declaration imports only the classes that the program uses from a particular package.
- The compiler uses a(n) \_\_\_\_\_ to locate the classes it needs in the classpath.
- The classpath for the compiler and JVM can be specified with the \_\_\_\_\_ option to the `javac` or `java` command, or by setting the \_\_\_\_\_ environment variable.
- `Set` methods are commonly called \_\_\_\_\_ because they typically change a value.
- A(n) \_\_\_\_\_ imports all static members of a class.
- The `public` methods of a class are also known as the class's \_\_\_\_\_ or \_\_\_\_\_.

## Answers to Self-Review Exercise

**8.1** a) -d. b) format. c) shadows. d) finalize. e) single-type-import. f) default constructor. g) toString. h) accessor methods, query methods. i) predicate. j) values. k) *has-a*. l) enum. m) static. n) single static import. o) principle of least privilege. p) final. q) package declaration. r) type-import-on-demand. s) class loader. t) -classpath, CLASSPATH. u) mutator methods. v) static import on demand. w) public services, public interface.

## Exercises

**8.2** Explain the notion of package access in Java. Explain the negative aspects of package access.

**8.3** What happens when a return type, even void, is specified for a constructor?

**8.4** (*Rectangle Class*) Create a class Rectangle with attributes length and width, each of which defaults to 1. Provide methods that calculate the rectangle's perimeter and area. It has set and get methods for both length and width. The set methods should verify that length and width are each floating-point numbers larger than 0.0 and less than 20.0. Write a program to test class Rectangle.

**8.5** (*Modifying the Internal Data Representation of a Class*) It would be perfectly reasonable for the Time2 class of Fig. 8.5 to represent the time internally as the number of seconds since midnight rather than the three integer values hour, minute and second. Clients could use the same public methods and get the same results. Modify the Time2 class of Fig. 8.5 to implement the Time2 as the number of seconds since midnight and show that no change is visible to the clients of the class.

**8.6** (*Savings Account Class*) Create class SavingsAccount. Use a static variable annualInterestRate to store the annual interest rate for all account holders. Each object of the class contains a private instance variable savingsBalance indicating the amount the saver currently has on deposit. Provide method calculateMonthlyInterest to calculate the monthly interest by multiplying the savingsBalance by annualInterestRate divided by 12—this interest should be added to savingsBalance. Provide a static method modifyInterestRate that sets the annualInterestRate to a new value. Write a program to test class SavingsAccount. Instantiate two savingsAccount objects, saver1 and saver2, with balances of \$2000.00 and \$3000.00, respectively. Set annualInterestRate to 4%, then calculate the monthly interest for each of 12 months and print the new balances for both savers. Next, set the annualInterestRate to 5%, calculate the next month's interest and print the new balances for both savers.

**8.7** (*Enhancing Class Time2*) Modify class Time2 of Fig. 8.5 to include a tick method that increments the time stored in a Time2 object by one second. Provide method incrementMinute to increment the minute by one and method incrementHour to increment the hour by one. Write a program that tests the tick method, the incrementMinute method and the incrementHour method to ensure that they work correctly. Be sure to test the following cases:

- a) incrementing into the next minute,
- b) incrementing into the next hour and
- c) incrementing into the next day (i.e., 11:59:59 PM to 12:00:00 AM).

**8.8** (*Enhancing Class Date*) Modify class Date of Fig. 8.7 to perform error checking on the initializer values for instance variables month, day and year (currently it validates only the month and day). Provide a method nextDay to increment the day by one. Write a program that tests method nextDay in a loop that prints the date during each iteration to illustrate that the method works correctly. Test the following cases:

- a) incrementing into the next month and
- b) incrementing into the next year.

**8.9** Rewrite the code in Fig. 8.14 to use a separate import declaration for each static member of class Math that's used in the example.

**8.10** Write an enum type `TrafficLight`, whose constants (`RED`, `GREEN`, `YELLOW`) take one parameter—the duration of the light. Write a program to test the `TrafficLight` enum so that it displays the enum constants and their durations.

**8.11** (*Complex Numbers*) Create a class called `Complex` for performing arithmetic with complex numbers. Complex numbers have the form

$$\text{realPart} + \text{imaginaryPart} * i$$

where  $i$  is

$$\sqrt{-1}$$

Write a program to test your class. Use floating-point variables to represent the private data of the class. Provide a constructor that enables an object of this class to be initialized when it's declared. Provide a no-argument constructor with default values in case no initializers are provided. Provide public methods that perform the following operations:

- Add two `Complex` numbers: The real parts are added together and the imaginary parts are added together.
- Subtract two `Complex` numbers: The real part of the right operand is subtracted from the real part of the left operand, and the imaginary part of the right operand is subtracted from the imaginary part of the left operand.
- Print `Complex` numbers in the form (*realPart*, *imaginaryPart*).

**8.12** (*Date and Time Class*) Create class `DateAndTime` that combines the modified `Time2` class of Exercise 8.7 and the modified `Date` class of Exercise 8.8. Modify method `incrementHour` to call method `nextDay` if the time is incremented into the next day. Modify methods `toString` and `toUniversalString` to output the date in addition to the time. Write a program to test the new class `DateAndTime`. Specifically, test incrementing the time to the next day.

**8.13** (*Set of Integers*) Create class `IntegerSet`. Each `IntegerSet` object can hold integers in the range 0–100. The set is represented by an array of `booleans`. Array element `a[i]` is `true` if integer  $i$  is in the set. Array element `a[j]` is `false` if integer  $j$  is not in the set. The no-argument constructor initializes the array to the “empty set” (i.e., all `false` values).

Provide the following methods: The static method `union` creates a set that's the set-theoretic union of two existing sets (i.e., an element of the new set's array is set to `true` if that element is `true` in either or both of the existing sets—otherwise, the new set's element is set to `false`). The static method `intersection` creates a set which is the set-theoretic intersection of two existing sets (i.e., an element of the new set's array is set to `false` if that element is `false` in either or both of the existing sets—otherwise, the new set's element is set to `true`). Method `insertElement` inserts a new integer  $k$  into a set (by setting `a[k]` to `true`). Method `deleteElement` deletes integer  $m$  (by setting `a[m]` to `false`). Method `toString` returns a `String` containing a set as a list of numbers separated by spaces. Include only those elements that are present in the set. Use `---` to represent an empty set. Method `isEqualTo` determines whether two sets are equal. Write a program to test class `IntegerSet`. Instantiate several `IntegerSet` objects. Test that all your methods work properly.

**8.14** (*Date Class*) Create class `Date` with the following capabilities:

- Output the date in multiple formats, such as
 

```
MM/DD/YYYY
June 14, 1992
DDD YYYY
```
- Use overloaded constructors to create `Date` objects initialized with dates of the formats in part (a). In the first case the constructor should receive three integer values. In the second case it should receive a `String` and two integer values. In the third case it should receive two integer values, the first of which represents the day number in the year.

[*Hint:* To convert the `String` representation of the month to a numeric value, compare `Strings` using the `equals` method. For example, if `s1` and `s2` are `Strings`, the method call `s1.equals( s2 )` returns `true` if the `Strings` are identical and otherwise returns `false`.]

**8.15** (*Rational Numbers*) Create a class called `Rational` for performing arithmetic with fractions. Write a program to test your class. Use integer variables to represent the private instance variables of the class—the numerator and the denominator. Provide a constructor that enables an object of this class to be initialized when it's declared. The constructor should store the fraction in reduced form. The fraction

$$2/4$$

is equivalent to  $1/2$  and would be stored in the object as 1 in the numerator and 2 in the denominator. Provide a no-argument constructor with default values in case no initializers are provided. Provide `public` methods that perform each of the following operations:

- Add two `Rational` numbers: The result of the addition should be stored in reduced form. Implement this as a `static` method.
- Subtract two `Rational` numbers: The result of the subtraction should be stored in reduced form. Implement this as a `static` method.
- Multiply two `Rational` numbers: The result of the multiplication should be stored in reduced form. Implement this as a `static` method.
- Divide two `Rational` numbers: The result of the division should be stored in reduced form. Implement this as a `static` method.
- Return a `String` representation of a `Rational` number in the form `a/b`, where `a` is the numerator and `b` is the denominator.
- Return a `String` representation of a `Rational` number in floating-point format. (Consider providing formatting capabilities that enable the user of the class to specify the number of digits of precision to the right of the decimal point.)

**8.16** (*Huge Integer Class*) Create a class `HugeInteger` which uses a 40-element array of digits to store integers as large as 40 digits each. Provide methods `parse`, `toString`, `add` and `subtract`. Method `parse` should receive a `String`, extract each digit using method `charAt` and place the integer equivalent of each digit into the integer array. For comparing `HugeInteger` objects, provide the following methods: `isEqualTo`, `isNotEqualTo`, `isGreaterThan`, `isLessThan`, `isGreaterThanOrEqualTo` and `isLessThanOrEqualTo`. Each of these is a predicate method that returns `true` if the relationship holds between the two `HugeInteger` objects and returns `false` if the relationship does not hold. Provide a predicate method `isZero`. If you feel ambitious, also provide methods `multiply`, `divide` and `remainder`. [*Note:* Primitive `boolean` values can be output as the word “true” or the word “false” with format specifier `%b`.]

**8.17** (*Tic-Tac-Toe*) Create a class `TicTacToe` that will enable you to write a program to play Tic-Tac-Toe. The class contains a private 3-by-3 two-dimensional array. Use an enumeration to represent the value in each cell of the array. The enumeration's constants should be named `X`, `O` and `EMPTY` (for a position that does not contain an `X` or an `O`). The constructor should initialize the board elements to `EMPTY`. Allow two human players. Wherever the first player moves, place an `X` in the specified square, and place an `O` wherever the second player moves. Each move must be to an empty square. After each move, determine whether the game has been won and whether it's a draw. If you feel ambitious, modify your program so that the computer makes the moves for one of the players. Also, allow the player to specify whether he or she wants to go first or second. If you feel exceptionally ambitious, develop a program that will play three-dimensional Tic-Tac-Toe on a 4-by-4-by-4 board [*Note:* This is an extremely challenging project!].

## Making a Difference

**8.18** (*Project: Emergency Response Class*) The North American emergency response service, 9-1-1, connects callers to a *local* Public Service Answering Point (PSAP). Traditionally, the PSAP would ask the caller for identification information—including the caller’s address, phone number and the nature of the emergency, then dispatch the appropriate emergency responders (such as the police, an ambulance or the fire department). *Enhanced 9-1-1 (or E9-1-1)* uses computers and databases to determine the caller’s physical address, directs the call to the nearest PSAP, and displays the caller’s phone number and address to the call taker. *Wireless Enhanced 9-1-1* provides call takers with identification information for wireless calls. Rolled out in two phases, the first phase required carriers to provide the wireless phone number and the location of the cell site or base station transmitting the call. The second phase required carriers to provide the location of the caller (using technologies such as GPS). To learn more about 9-1-1, visit [www.fcc.gov/pshs/services/911-services/Wel-come.htm](http://www.fcc.gov/pshs/services/911-services/Wel-come.htm) and [people.howstuffworks.com/9-1-1.htm](http://people.howstuffworks.com/9-1-1.htm).

An important part of creating a class is determining the class’s attributes (instance variables). For this class design exercise, research 9-1-1 services on the Internet. Then, design a class called *Emergency* that might be used in an object-oriented 9-1-1 emergency response system. List the attributes that an object of this class might use to represent the emergency. For example, the class might include information on who reported the emergency (including their phone number), the location of the emergency, the time of the report, the nature of the emergency, the type of response and the status of the response. The class attributes should completely describe the nature of the problem and what’s happening to resolve that problem.

# Object-Oriented Programming: Inheritance

# 9

*Say not you know another  
entirely,  
till you have divided an  
inheritance with him.*

—Johann Kasper Lavater

*This method is to define as the  
number of a class the class of all  
classes similar to the given class.*

—Bertrand Russell

## Objectives

In this chapter you'll learn:

- How inheritance promotes software reusability.
- The notions of superclasses and subclasses and the relationship between them.
- To use keyword **extends** to create a class that inherits attributes and behaviors from another class.
- To use access modifier **protected** to give subclass methods access to superclass members.
- To access superclass members with **super**.
- How constructors are used in inheritance hierarchies.
- The methods of class **Object**, the direct or indirect superclass of all classes.

- 9.1 Introduction
- 9.2 Superclasses and Subclasses
- 9.3 protected Members
- 9.4 Relationship between Superclasses and Subclasses
  - 9.4.1 Creating and Using a `CommissionEmployee` Class
  - 9.4.2 Creating and Using a `BasePlusCommissionEmployee` Class
  - 9.4.3 Creating a `CommissionEmployee–BasePlusCommissionEmployee` Inheritance Hierarchy
  - 9.4.4 `CommissionEmployee–BasePlusCommissionEmployee` Inheritance Hierarchy Using `protected` Instance Variables
  - 9.4.5 `CommissionEmployee–BasePlusCommissionEmployee` Inheritance Hierarchy Using `private` Instance Variables
- 9.5 Constructors in Subclasses
- 9.6 Software Engineering with Inheritance
- 9.7 Class Object
- 9.8 (Optional) GUI and Graphics Case Study: Displaying Text and Images Using `Labels`
- 9.9 Wrap-Up

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises*

## 9.1 Introduction

This chapter continues our discussion of object-oriented programming (OOP) by introducing one of its primary capabilities—**inheritance**, which is a form of software reuse in which a new class is created by absorbing an existing class’s members and embellishing them with new or modified capabilities. With inheritance, you can save time during program development by basing new classes on existing proven and debugged high-quality software. This also increases the likelihood that a system will be implemented and maintained effectively.

When creating a class, rather than declaring completely new members, you can designate that the new class should inherit the members of an existing class. The existing class is called the **superclass**, and the new class is the **subclass**. (The C++ programming language refers to the superclass as the **base class** and the subclass as the **derived class**.) Each subclass can become a superclass for future subclasses.

A subclass can add its own fields and methods. Therefore, a subclass is *more specific* than its superclass and represents a more specialized group of objects. The subclass exhibits the behaviors of its superclass and can modify those behaviors so that they operate appropriately for the subclass. This is why inheritance is sometimes referred to as **specialization**.

The **direct superclass** is the superclass from which the subclass explicitly inherits. An **indirect superclass** is any class above the direct superclass in the **class hierarchy**, which defines the inheritance relationships between classes. In Java, the class hierarchy begins with class `Object` (in package `java.lang`), which *every* class in Java directly or indirectly **extends** (or “inherits from”). Section 9.7 lists the methods of class `Object` that are inherited by all other Java classes. Java supports only **single inheritance**, in which each class is derived from exactly *one* direct superclass. Unlike C++, Java does *not* support multiple inheritance (which occurs when a class is derived from more than one direct superclass). Chapter 10, Object-Oriented Programming: Polymorphism, explains how to use Java interfaces to realize many of the benefits of multiple inheritance while avoiding the associated problems.

We distinguish between the *is-a relationship* and the *has-a relationship*. *Is-a* represents inheritance. In an *is-a* relationship, *an object of a subclass can also be treated as an object of its superclass*—e.g., a car *is a* vehicle. By contrast, *has-a* represents composition (see Chapter 8). In a *has-a* relationship, *an object contains as members references to other objects*—e.g., a car *has a* steering wheel (and a car object has a reference to a steering-wheel object).

New classes can inherit from classes in **class libraries**. Organizations develop their own class libraries and can take advantage of others available worldwide. Some day, most new software likely will be constructed from **standardized reusable components**, just as automobiles and most computer hardware are constructed today. This will facilitate the development of more powerful, abundant and economical software.

## 9.2 Superclasses and Subclasses

Often, an object of one class *is an* object of another class as well. Figure 9.1 lists several simple examples of superclasses and subclasses—superclasses tend to be “more general” and subclasses “more specific.” For example, a CarLoan *is a* Loan as are HomeImprovementLoans and MortgageLoans. Thus, in Java, class CarLoan can be said to inherit from class Loan. In this context, class Loan is a superclass and class CarLoan is a subclass. A CarLoan *is a* specific type of Loan, but it’s incorrect to claim that every Loan *is a* CarLoan—the Loan could be any type of loan.

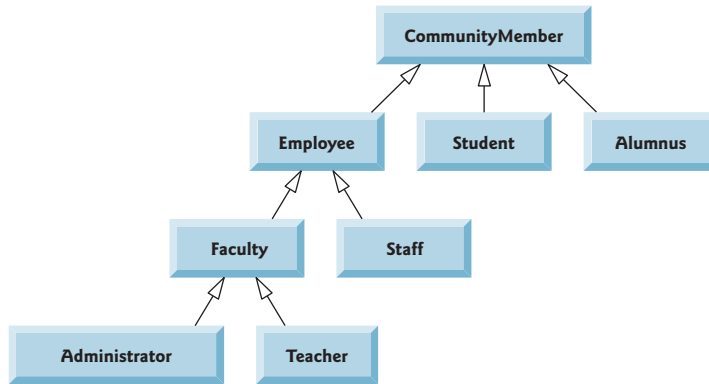

| Superclass  | Subclasses                                 |
|-------------|--------------------------------------------|
| Student     | GraduateStudent, UndergraduateStudent      |
| Shape       | Circle, Triangle, Rectangle, Sphere, Cube  |
| Loan        | CarLoan, HomeImprovementLoan, MortgageLoan |
| Employee    | Faculty, Staff                             |
| BankAccount | CheckingAccount, SavingsAccount            |

**Fig. 9.1** | Inheritance examples.

Because every subclass object *is an* object of its superclass, and one superclass can have many subclasses, the set of objects represented by a superclass is often larger than the set of objects represented by any of its subclasses. For example, the superclass Vehicle represents all vehicles, including cars, trucks, boats, bicycles and so on. By contrast, subclass Car represents a smaller, more specific subset of vehicles.

### University Community Member Hierarchy

Inheritance relationships form treelike hierarchical structures. A superclass exists in a hierarchical relationship with its subclasses. Let’s develop a sample class hierarchy (Fig. 9.2), also called an **inheritance hierarchy**. A university community has thousands of members, including employees, students and alumni. Employees are either faculty or staff members. Faculty members are either administrators (e.g., deans and department chairpersons) or teachers. The hierarchy could contain many other classes. For example, students can be graduate or undergraduate students. Undergraduate students can be freshmen, sophomores, juniors or seniors.

**Fig. 9.2** | Inheritance hierarchy for university CommunityMembers.

Each arrow in the hierarchy represents an *is-a* relationship. As we follow the arrows upward in this class hierarchy, we can state, for instance, that “an Employee *is a* CommunityMember” and “a Teacher *is a* Faculty member.” CommunityMember is the direct superclass of Employee, Student and Alumnus and is an indirect superclass of all the other classes in the diagram. Starting from the bottom, you can follow the arrows and apply the *is-a* relationship up to the topmost superclass. For example, an Administrator *is a* Faculty member, *is an* Employee, *is a* CommunityMember and, of course, *is an* Object.

### Shape Hierarchy

Now consider the Shape inheritance hierarchy in Fig. 9.3. This hierarchy begins with superclass Shape, which is extended by subclasses TwoDimensionalShape and ThreeDimensionalShape—Shapes are either TwoDimensionalShapes or ThreeDimensionalShapes. The third level of this hierarchy contains specific types of TwoDimensionalShapes and ThreeDimensionalShapes. As in Fig. 9.2, we can follow the arrows from the bottom of the diagram to the topmost superclass in this class hierarchy to identify several *is-a* relationships. For instance, a Triangle *is a* TwoDimensionalShape and *is a* Shape, while a Sphere *is a* ThreeDimensionalShape and *is a* Shape. This hierarchy could contain many other classes. For example, ellipses and trapezoids are TwoDimensionalShapes.

**Fig. 9.3** | Inheritance hierarchy for Shapes.

Not every class relationship is an inheritance relationship. In Chapter 8, we discussed the *has-a* relationship, in which classes have members that are references to objects of other classes. Such relationships create classes by composition of existing classes. For example, given the classes `Employee`, `BirthDate` and `TelephoneNumber`, it's improper to say that an `Employee` *is a* `BirthDate` or that an `Employee` *is a* `TelephoneNumber`. However, an `Employee` *has a* `BirthDate`, and an `Employee` *has a* `TelephoneNumber`.

It's possible to treat superclass objects and subclass objects similarly—their commonalities are expressed in the superclass's members. Objects of all classes that extend a common superclass can be treated as objects of that superclass—such objects have an *is-a* relationship with the superclass. Later in this chapter and in Chapter 10, we consider many examples that take advantage of the *is-a* relationship.

A subclass can customize methods that it inherits from its superclass. To do this, the subclass **overrides** (redefines) the superclass method with an appropriate implementation, as we'll see often in the chapter's code examples.

## 9.3 protected Members

Chapter 8 discussed access modifiers `public` and `private`. A class's `public` members are accessible wherever the program has a reference to an object of that class or one of its subclasses. A class's `private` members are accessible only within the class itself. In this section, we introduce access modifier **protected**. Using `protected` access offers an intermediate level of access between `public` and `private`. A superclass's `protected` members can be accessed by members of that superclass, by members of its subclasses and by members of other classes in the same package—`protected` members also have package access.

All `public` and `protected` superclass members retain their original access modifier when they become members of the subclass—`public` members of the superclass become `public` members of the subclass, and `protected` members of the superclass become `protected` members of the subclass. A superclass's `private` members are not accessible outside the class itself. Rather, they're *hidden* in its subclasses and can be accessed only through the `public` or `protected` methods inherited from the superclass.

Subclass methods can refer to `public` and `protected` members inherited from the superclass simply by using the member names. When a subclass method overrides an inherited superclass method, the *superclass* method can be accessed from the *subclass* by preceding the superclass method name with keyword **super** and a dot (`.`) separator. We discuss accessing overridden members of the superclass in Section 9.4.

### Software Engineering Observation 9.1

*Methods of a subclass cannot directly access private members of their superclass. A subclass can change the state of private superclass instance variables only through non-private methods provided in the superclass and inherited by the subclass.*

### Software Engineering Observation 9.2

*Declaring private instance variables helps you test, debug and correctly modify systems. If a subclass could access its superclass's private instance variables, classes that inherit from that subclass could access the instance variables as well. This would propagate access to what should be private instance variables, and the benefits of information hiding would be lost.*

## 9.4 Relationship between Superclasses and Subclasses

We now use an inheritance hierarchy containing types of employees in a company's payroll application to discuss the relationship between a superclass and its subclass. In this company, commission employees (who will be represented as objects of a superclass) are paid a percentage of their sales, while base-salaried commission employees (who will be represented as objects of a subclass) receive a base salary *plus* a percentage of their sales.

We divide our discussion of the relationship between these classes into five examples. The first declares class `CommissionEmployee`, which directly inherits from class `Object` and declares as `private` instance variables a first name, last name, social security number, commission rate and gross (i.e., total) sales amount.

The second example declares class `BasePlusCommissionEmployee`, which also directly inherits from class `Object` and declares as `private` instance variables a first name, last name, social security number, commission rate, gross sales amount *and* base salary. We create this class by *writing every line of code* the class requires—we'll soon see that it's much more efficient to create it by inheriting from class `CommissionEmployee`.

The third example declares a new `BasePlusCommissionEmployee` class that *extends* class `CommissionEmployee` (i.e., a `BasePlusCommissionEmployee` *is a* `CommissionEmployee` who also has a base salary). This *software reuse lets us write less code* when developing the new subclass. In this example, class `BasePlusCommissionEmployee` attempts to access class `CommissionEmployee`'s `private` members—this results in compilation errors, because the subclass cannot access the superclass's `private` instance variables.

The fourth example shows that if `CommissionEmployee`'s instance variables are declared as `protected`, the `BasePlusCommissionEmployee` subclass can access that data directly. Both `BasePlusCommissionEmployee` classes contain identical functionality, but we show how the inherited version is easier to create and manage.

After we discuss the convenience of using `protected` instance variables, we create the fifth example, which sets the `CommissionEmployee` instance variables back to `private` to enforce good software engineering. Then we show how the `BasePlusCommissionEmployee` subclass can use `CommissionEmployee`'s `public` methods to manipulate (in a controlled manner) the `private` instance variables inherited from `CommissionEmployee`.

### 9.4.1 Creating and Using a `CommissionEmployee` Class

We begin by declaring class `CommissionEmployee` (Fig. 9.4). Line 4 begins the class declaration and indicates that class `CommissionEmployee` **extends** (i.e., inherits from) class **Object** (from package `java.lang`). This causes class `CommissionEmployee` to inherit the class `Object`'s methods—class `Object` does not have any fields. If you don't explicitly specify which class a new class extends, the class extends `Object` implicitly. For this reason, you typically will not include “extends `Object`” in your code—we do so in this example only for demonstration purposes.

#### *Overview of Class `CommissionEmployee`'s Methods and Instance Variables*

Class `CommissionEmployee`'s `public` services include a constructor (lines 13–22) and methods `earnings` (lines 93–96) and `toString` (lines 99–107). Lines 25–90 declare `public` *get* and *set* methods for the class's instance variables (declared in lines 6–10) `firstName`, `lastName`, `socialSecurityNumber`, `grossSales` and `commissionRate`. The class declares its instance variables as `private`, so objects of other classes cannot directly access

these variables. Declaring instance variables as *private* and providing *get* and *set* methods to manipulate and validate them helps enforce good software engineering. Methods *setGrossSales* and *setCommissionRate*, for example, validate their arguments before assigning the values to instance variables *grossSales* and *commissionRate*. In a real-world, business-critical application, we'd also perform validation in the class's other *set* methods.

```

1 // Fig. 9.4: CommissionEmployee.java
2 // CommissionEmployee class represents an employee paid a
3 // percentage of gross sales.
4 public class CommissionEmployee extends Object ← define herencia
5 {
6     private String firstName;
7     private String lastName;
8     private String socialSecurityNumber;
9     private double grossSales; // gross weekly sales
10    private double commissionRate; // commission percentage
11
12    // five-argument constructor
13    public CommissionEmployee( String first, String last, String ssn,
14        double sales, double rate )
15    {
16        // implicit call to Object constructor occurs here
17        firstName = first;
18        lastName = last;
19        socialSecurityNumber = ssn;
20        setGrossSales( sales ); // validate and store gross sales
21        setCommissionRate( rate ); // validate and store commission rate
22    } // end five-argument CommissionEmployee constructor
23
24    // set first name
25    public void setFirstName( String first )
26    {
27        firstName = first; // should validate
28    } // end method setFirstName
29
30    // return first name
31    public String getFirstName()
32    {
33        return firstName;
34    } // end method getFirstName
35
36    // set last name
37    public void setLastName( String last )
38    {
39        lastName = last; // should validate
40    } // end method setLastName
41
42    // return last name
43    public String getLastName()
44    {

101 {
102     return String.format( "%s: %s %s\n%s: %s\n%s: %.2f\n%s: %.2f",
103         "commission employee", firstName, lastName,
104         "social security number", socialSecurityNumber,
105         "gross sales", grossSales,
106         "commission rate", commissionRate );
107 } // end method toString
108 } // end class CommissionEmployee
```

**Fig. 9.4** | CommissionEmployee class represents an employee paid a percentage of gross sales. (Part 3 of 3.)

### Class CommissionEmployee’s Constructor

Constructors are *not* inherited, so class CommissionEmployee does not inherit class Object’s constructor. However, a superclass’s constructors are still available to subclasses. In fact, *the first task of any subclass constructor is to call its direct superclass’s constructor*, either explicitly or implicitly (if no constructor call is specified), to ensure that the instance variables inherited from the superclass are initialized properly. In this example, class CommissionEmployee’s constructor calls class Object’s constructor implicitly. The syntax for calling a superclass constructor explicitly is discussed in Section 9.4.3. If the code does not include an explicit call to the superclass constructor, Java *implicitly* calls the superclass’s default or no-argument constructor. The comment in line 16 of Fig. 9.4 indicates where the implicit call to the superclass Object’s default constructor is made (you do not write the code for this call). Object’s default (empty) constructor does nothing. Even if a class does not have constructors, the default constructor that the compiler implicitly declares for the class will call the superclass’s default or no-argument constructor.

After the implicit call to Object’s constructor, lines 17–21 of CommissionEmployee’s constructor assign values to the class’s instance variables. We do not validate the values of arguments first, last and ssn before assigning them to the corresponding instance variables. We could validate the first and last names—perhaps to ensure that they’re of a reasonable length. Similarly, a social security number could be validated using regular expressions (Section 16.7) to ensure that it contains nine digits, with or without dashes (e.g., 123-45-6789 or 123456789).

### Class CommissionEmployee’s earnings Method

Method earnings (lines 93–96) calculates a CommissionEmployee’s earnings. Line 95 multiplies the commissionRate by the grossSales and returns the result.

### Class CommissionEmployee’s toString Method and the @Override Annotation

Method toString (lines 99–107) is special—it’s one of the methods that *every* class inherits directly or indirectly from class Object (summarized in Section 9.7). Method toString returns a String representing an object. It’s called implicitly whenever an object must be converted to a String representation, such as when an object is output by printf or output by String method format via the %s format specifier. Class Object’s toString method returns a String that includes the name of the object’s class. It’s primarily a placeholder

that can be overridden by a subclass to specify an appropriate `String` representation of the data in a subclass object. Method `toString` of class `CommissionEmployee` overrides (redefines) class `Object`'s `toString` method. When invoked, `CommissionEmployee`'s `toString` method uses `String` method `format` to return a `String` containing information about the `CommissionEmployee`. To override a superclass method, a subclass must declare a method with the same signature (method name, number of parameters, parameter types and order of parameter types) as the superclass method—`Object`'s `toString` method takes no parameters, so `CommissionEmployee` declares `toString` with no parameters.

Line 99 uses the **@Override annotation** to indicate that method `toString` should override a superclass method. Annotations have several purposes. For example, when you attempt to override a superclass method, common errors include naming the subclass method incorrectly, or using the wrong number or types of parameters in the parameter list. Each of these problems creates an *unintentional overload* of the superclass method. If you then attempt to call the method on a subclass object, the superclass's version is invoked and the subclass version is ignored—potentially leading to subtle logic errors. When the compiler encounters a method declared with **@Override**, it compares the method's signature with the superclass's method signatures. If there isn't an exact match, the compiler issues an error message, such as "method does not override or implement a method from a supertype." This indicates that you've accidentally overloaded a superclass method. You can then fix your method's signature so that it matches one in the superclass.

As you'll see when we discuss web applications and web services in Chapters 29–31, annotations can also add complex support code to your classes to simplify the development process and can be used by servers to configure certain aspects of web applications.

### Common Programming Error 9.1

*Using an incorrect method signature when attempting to override a superclass method causes an unintentional method overload that can lead to subtle logic errors.*

### Error-Prevention Tip 9.1

*Declare overridden methods with the **@Override** annotation to ensure at compilation time that you defined their signatures correctly. It's always better to find errors at compile time rather than at runtime.*

### Common Programming Error 9.2

*It's a syntax error to override a method with a more restricted access modifier—a `public` method of the superclass cannot become a `protected` or `private` method in the subclass; a `protected` method of the superclass cannot become a `private` method in the subclass. Doing so would break the is-a relationship in which it's required that all subclass objects be able to respond to method calls that are made to `public` methods declared in the superclass. If a `public` method, for example, could be overridden as a `protected` or `private` method, the subclass objects would not be able to respond to the same method calls as superclass objects. Once a method is declared `public` in a superclass, the method remains `public` for all that class's direct and indirect subclasses.*

## Class `CommissionEmployeeTest`

Figure 9.5 tests class `CommissionEmployee`. Lines 9–10 instantiate a `CommissionEmployee` object and invoke `CommissionEmployee`'s constructor (lines 13–22 of Fig. 9.4) to initialize

it with "Sue" as the first name, "Jones" as the last name, "222-22-2222" as the social security number, 10000 as the gross sales amount and .06 as the commission rate. Lines 15–24 use `CommissionEmployee`'s *get* methods to retrieve the object's instance-variable values for output. Lines 26–27 invoke the object's methods `setGrossSales` and `setCommissionRate` to change the values of instance variables `grossSales` and `commissionRate`. Lines 29–30 output the `String` representation of the updated `CommissionEmployee`. When an object is output using the `%s` format specifier, the object's `toString` method is invoked implicitly to obtain the object's `String` representation. [*Note:* In this chapter, we do not use the earnings methods of our classes—they're used extensively in Chapter 10.]

```

1 // Fig. 9.5: CommissionEmployeeTest.java
2 // CommissionEmployee class test program.
3
4 public class CommissionEmployeeTest
5 {
6     public static void main( String[] args )
7     {
8         // instantiate CommissionEmployee object
9         CommissionEmployee employee = new CommissionEmployee(
10            "Sue", "Jones", "222-22-2222", 10000, .06 );
11
12        // get commission employee data
13        System.out.println(
14            "Employee information obtained by get methods: \n" );
15        System.out.printf( "%s %s\n", "First name is",
16            employee.getFirstName() );
17        System.out.printf( "%s %s\n", "Last name is",
18            employee.getLastName() );
19        System.out.printf( "%s %s\n", "Social security number is",
20            employee.getSocialSecurityNumber() );
21        System.out.printf( "%s %.2f\n", "Gross sales is",
22            employee.getGrossSales() );
23        System.out.printf( "%s %.2f\n", "Commission rate is",
24            employee.getCommissionRate() );
25
26        employee.setGrossSales( 500 ); // set gross sales
27        employee.setCommissionRate( .1 ); // set commission rate
28
29        System.out.printf( "\n%s:\n\n%s\n",
30            "Updated employee information obtained by toString", employee );
31    } // end main
32 } // end class CommissionEmployeeTest

```

envia un objeto xq todo objeto hereda el metodo toString

```

Employee information obtained by get methods:

First name is Sue
Last name is Jones
Social security number is 222-22-2222
Gross sales is 10000.00
Commission rate is 0.06

```

**Fig. 9.5** | `CommissionEmployee` class test program. (Part 1 of 2.)

Updated employee information obtained by toString:

```
commission employee: Sue Jones
social security number: 222-22-2222
gross sales: 500.00
commission rate: 0.10
```

**Fig. 9.5** | CommissionEmployee class test program. (Part 2 of 2.)

### 9.4.2 Creating and Using a BasePlusCommissionEmployee Class

We now discuss the second part of our introduction to inheritance by declaring and testing (a completely new and independent) class `BasePlusCommissionEmployee` (Fig. 9.6), which contains a first name, last name, social security number, gross sales amount, commission rate *and* base salary. Class `BasePlusCommissionEmployee`'s public services include a `BasePlusCommissionEmployee` constructor (lines 15–25) and methods `earnings` (lines 112–115) and `toString` (lines 118–127). Lines 28–109 declare public *get* and *set* methods for the class's private instance variables (declared in lines 7–12) `firstName`, `lastName`, `socialSecurityNumber`, `grossSales`, `commissionRate` *and* `baseSalary`. These variables and methods encapsulate all the necessary features of a base-salaried commission employee. Note the *similarity* between this class and class `CommissionEmployee` (Fig. 9.4)—in this example, we'll not yet exploit that similarity.

```
1 // Fig. 9.6: BasePlusCommissionEmployee.java
2 // BasePlusCommissionEmployee class represents an employee who receives
3 // a base salary in addition to commission.
4
5 public class BasePlusCommissionEmployee
6 {
7     private String firstName;
8     private String lastName;
9     private String socialSecurityNumber;
10    private double grossSales; // gross weekly sales
11    private double commissionRate; // commission percentage
12    private double baseSalary; // base salary per week
13
14    // six-argument constructor
15    public BasePlusCommissionEmployee( String first, String last,
16        String ssn, double sales, double rate, double salary )
17    {
18        // implicit call to Object constructor occurs here
19        firstName = first;
20        lastName = last;
21        socialSecurityNumber = ssn;
22        setGrossSales( sales ); // validate and store gross sales
23        setCommissionRate( rate ); // validate and store commission rate
24        setBaseSalary( salary ); // validate and store base salary
25    } // end six-argument BasePlusCommissionEmployee constructor
```

**Fig. 9.6** | `BasePlusCommissionEmployee` class represents an employee who receives a base salary in addition to a commission. (Part 1 of 3.)

```
26
27 // set first name
28 public void setFirstName( String first )
29 {
30     firstName = first; // should validate
31 } // end method setFirstName
32
33 // return first name
34 public String getFirstName()
35 {
36     return firstName;
37 } // end method getFirstName
38
39 // set last name
40 public void setLastName( String last )
41 {
42     lastName = last; // should validate
43 } // end method setLastName
44
45 // return last name
46 public String getLastName()
47 {
48     return lastName;
49 } // end method getLastName
50
51 // set social security number
52 public void setSocialSecurityNumber( String ssn )
53 {
54     socialSecurityNumber = ssn; // should validate
55 } // end method setSocialSecurityNumber
56
57 // return social security number
58 public String getSocialSecurityNumber()
59 {
60     return socialSecurityNumber;
61 } // end method getSocialSecurityNumber
62
63 // set gross sales amount
64 public void setGrossSales( double sales )
65 {
66     if ( sales >= 0.0 )
67         grossSales = sales;
68     else
69         throw new IllegalArgumentException(
70             "Gross sales must be >= 0.0" );
71 } // end method setGrossSales
72
73 // return gross sales amount
74 public double getGrossSales()
75 {
76     return grossSales;
77 } // end method getGrossSales
```

**Fig. 9.6** | BasePlusCommissionEmployee class represents an employee who receives a base salary in addition to a commission. (Part 2 of 3.)

```

78
79 // set commission rate
80 public void setCommissionRate( double rate )
81 {
82     if ( rate > 0.0 && rate < 1.0 )
83         commissionRate = rate;
84     else
85         throw new IllegalArgumentException(
86             "Commission rate must be > 0.0 and < 1.0" );
87 } // end method setCommissionRate
88
89 // return commission rate
90 public double getCommissionRate()
91 {
92     return commissionRate;
93 } // end method getCommissionRate
94
95 // set base salary
96 public void setBaseSalary( double salary )
97 {
98     if ( salary >= 0.0 )
99         baseSalary = salary;
100    else
101        throw new IllegalArgumentException(
102            "Base salary must be >= 0.0" );
103 } // end method setBaseSalary
104
105 // return base salary
106 public double getBaseSalary()
107 {
108     return baseSalary;
109 } // end method getBaseSalary
110
111 // calculate earnings
112 public double earnings()
113 {
114     return baseSalary + ( commissionRate * grossSales );
115 } // end method earnings
116
117 // return String representation of BasePlusCommissionEmployee
118 @Override // indicates that this method overrides a superclass method
119 public String toString()
120 {
121     return String.format(
122         "%s: %s %s\n%s: %s\n%s: %.2f\n%s: %.2f\n%s: %.2f",
123         "base-salaried commission employee", firstName, lastName,
124         "social security number", socialSecurityNumber,
125         "gross sales", grossSales, "commission rate", commissionRate,
126         "base salary", baseSalary );
127 } // end method toString
128 } // end class BasePlusCommissionEmployee

```

**Fig. 9.6** | BasePlusCommissionEmployee class represents an employee who receives a base salary in addition to a commission. (Part 3 of 3.)

Class `BasePlusCommissionEmployee` does not specify “extends `Object`” in line 5, so the class implicitly extends `Object`. Also, like class `CommissionEmployee`’s constructor (lines 13–22 of Fig. 9.4), class `BasePlusCommissionEmployee`’s constructor invokes class `Object`’s default constructor implicitly, as noted in the comment in line 18.

Class `BasePlusCommissionEmployee`’s `earnings` method (lines 112–115) returns the result of adding the `BasePlusCommissionEmployee`’s base salary to the product of the commission rate and the employee’s gross sales.

Class `BasePlusCommissionEmployee` overrides `Object` method `toString` to return a `String` containing the `BasePlusCommissionEmployee`’s information. Once again, we use format specifier `%.2f` to format the gross sales, commission rate and base salary with two digits of precision to the right of the decimal point (line 122).

### Testing Class `BasePlusCommissionEmployee`

Figure 9.7 tests class `BasePlusCommissionEmployee`. Lines 9–11 create a `BasePlusCommissionEmployee` object and pass “Bob”, “Lewis”, “333-33-3333”, 5000, .04 and 300 to the constructor as the first name, last name, social security number, gross sales, commission rate and base salary, respectively. Lines 16–27 use `BasePlusCommissionEmployee`’s `get` methods to retrieve the values of the object’s instance variables for output. Line 29 invokes the object’s `setBaseSalary` method to change the base salary. Method `setBaseSalary` (Fig. 9.6, lines 88–91) ensures that instance variable `baseSalary` is not assigned a negative value. Lines 31–33 of Fig. 9.7 invoke method `toString` explicitly to get the object’s `String` representation.

---

```

1 // Fig. 9.7: BasePlusCommissionEmployeeTest.java
2 // BasePlusCommissionEmployee test program.
3
4 public class BasePlusCommissionEmployeeTest
5 {
6     public static void main( String[] args )
7     {
8         // instantiate BasePlusCommissionEmployee object
9         BasePlusCommissionEmployee employee =
10            new BasePlusCommissionEmployee(
11                "Bob", "Lewis", "333-33-3333", 5000, .04, 300 );
12
13        // get base-salaried commission employee data
14        System.out.println(
15            "Employee information obtained by get methods: \n" );
16        System.out.printf( "%s %s\n", "First name is",
17            employee.getFirstName() );
18        System.out.printf( "%s %s\n", "Last name is",
19            employee.getLastName() );
20        System.out.printf( "%s %s\n", "Social security number is",
21            employee.getSocialSecurityNumber() );
22        System.out.printf( "%s %.2f\n", "Gross sales is",
23            employee.getGrossSales() );
24        System.out.printf( "%s %.2f\n", "Commission rate is",
25            employee.getCommissionRate() );
26        System.out.printf( "%s %.2f\n", "Base salary is",
27            employee.getBaseSalary() );

```

---

**Fig. 9.7** | `BasePlusCommissionEmployee` test program. (Part I of 2.)

```

28
29     employee.setBaseSalary( 1000 ); // set base salary
30
31     System.out.printf( "\n%s:\n\n%s\n",
32         "Updated employee information obtained by toString",
33         employee.toString() );
34     } // end main
35 } // end class BasePlusCommissionEmployeeTest

```

Employee information obtained by get methods:

```

First name is Bob
Last name is Lewis
Social security number is 333-33-3333
Gross sales is 5000.00
Commission rate is 0.04
Base salary is 300.00

```

Updated employee information obtained by toString:

```

base-salaried commission employee: Bob Lewis
social security number: 333-33-3333
gross sales: 5000.00
commission rate: 0.04
base salary: 1000.00

```

**Fig. 9.7** | BasePlusCommissionEmployee test program. (Part 2 of 2.)

### *Notes on Class BasePlusCommissionEmployee*

Much of class `BasePlusCommissionEmployee`'s code (Fig. 9.6) is similar, or identical, to that of class `CommissionEmployee` (Fig. 9.4). For example, private instance variables `firstName` and `lastName` and methods `setFirstName`, `getFirstName`, `setLastName` and `getLastName` are identical to those of class `CommissionEmployee`. The classes also both contain private instance variables `socialSecurityNumber`, `commissionRate` and `grossSales`, and corresponding *get* and *set* methods. In addition, the `BasePlusCommissionEmployee` constructor is almost identical to that of class `CommissionEmployee`, except that `BasePlusCommissionEmployee`'s constructor also sets the `baseSalary`. The other additions to class `BasePlusCommissionEmployee` are private instance variable `baseSalary` and methods `setBaseSalary` and `getBaseSalary`. Class `BasePlusCommissionEmployee`'s `toString` method is nearly identical to that of class `CommissionEmployee` except that it also outputs instance variable `baseSalary` with two digits of precision to the right of the decimal point.

We literally *copied* code from class `CommissionEmployee` and *pasted* it into class `BasePlusCommissionEmployee`, then modified class `BasePlusCommissionEmployee` to include a base salary and methods that manipulate the base salary. This “copy-and-paste” approach is often error prone and time consuming. Worse yet, it spreads copies of the same code throughout a system, creating a code-maintenance nightmare. Is there a way to “absorb” the instance variables and methods of one class in a way that makes them part of other classes *without duplicating code*? Next we answer this question, using a more elegant approach to building classes that emphasizes the benefits of inheritance.

### Software Engineering Observation 9.3

With inheritance, the common instance variables and methods of all the classes in the hierarchy are declared in a superclass. When changes are made for these common features in the superclass—subclasses then inherit the changes. Without inheritance, changes would need to be made to all the source-code files that contain a copy of the code in question.

## 9.4.3 Creating a CommissionEmployee–BasePlusCommissionEmployee Inheritance Hierarchy

Now we redeclare class `BasePlusCommissionEmployee` (Fig. 9.8) to *extend* class `CommissionEmployee` (Fig. 9.4). A `BasePlusCommissionEmployee` object *is a* `CommissionEmployee`, because inheritance passes on class `CommissionEmployee`'s capabilities. Class `BasePlusCommissionEmployee` also has instance variable `baseSalary` (Fig. 9.8, line 6). Keyword `extends` (line 4) indicates inheritance. `BasePlusCommissionEmployee` *inherits* `CommissionEmployee`'s instance variables and methods, but only the superclass's `public` and `protected` members are directly accessible in the subclass. The `CommissionEmployee` constructor is *not* inherited. So, the `public` `BasePlusCommissionEmployee` services include its constructor (lines 9–16), `public` methods inherited from `CommissionEmployee`, and methods `setBaseSalary` (lines 19–26), `getBaseSalary` (lines 29–32), `earnings` (lines 35–40) and `toString` (lines 43–53). Methods `earnings` and `toString` *override* the corresponding methods in class `CommissionEmployee` because their superclass versions do not properly calculate a `BasePlusCommissionEmployee`'s earnings or return an appropriate `String` representation.

```

1 // Fig. 9.8: BasePlusCommissionEmployee.java
2 // private superclass members cannot be accessed in a subclass.
3
4 public class BasePlusCommissionEmployee extends CommissionEmployee
5 {
6     private double baseSalary; // base salary per week
7
8     // six-argument constructor
9     public BasePlusCommissionEmployee( String first, String last,
10        String ssn, double sales, double rate, double salary )
11     {
12         // explicit call to superclass CommissionEmployee constructor
13         super( first, last, ssn, sales, rate );
14
15         setBaseSalary( salary ); // validate and store base salary
16     } // end six-argument BasePlusCommissionEmployee constructor
17
18     // set base salary
19     public void setBaseSalary( double salary )
20     {
21         if ( salary >= 0.0 )
22             baseSalary = salary;
23         else
24             throw new IllegalArgumentException(
25                 "Base salary must be >= 0.0" );
26     } // end method setBaseSalary

```

### *A Subclass's Constructor Must Call Its Superclass's Constructor*

Each subclass constructor must implicitly or explicitly call its superclass constructor to initialize the instance variables inherited from the superclass. Line 13 in `BasePlusCommissionEmployee`'s six-argument constructor (lines 9–16) explicitly calls class `CommissionEmployee`'s five-argument constructor (declared at lines 13–22 of Fig. 9.4) to initialize the superclass portion of a `BasePlusCommissionEmployee` object (i.e., variables `firstName`, `lastName`, `socialSecurityNumber`, `grossSales` and `commissionRate`). We do this by using the **superclass constructor call syntax**—keyword `super`, followed by a set of parentheses containing the superclass constructor arguments. The arguments `first`, `last`, `ssn`, `sales` and `rate` are used to initialize superclass members `firstName`, `lastName`, `socialSecurityNumber`, `grossSales` and `commissionRate`, respectively. If `BasePlusCommissionEmployee`'s constructor did not invoke the superclass's constructor explicitly, Java would attempt to invoke the superclass's no-argument or default constructor. Class `CommissionEmployee` does not have such a constructor, so the compiler would issue an error. The explicit superclass constructor call in line 13 of Fig. 9.8 must be the *first* statement in the subclass constructor's body. When a superclass contains a no-argument constructor, you can use `super()` to call that constructor explicitly, but this is rarely done.

### *BasePlusCommissionEmployee Method Earnings*

The compiler generates errors for line 39 because superclass `CommissionEmployee`'s instance variables `commissionRate` and `grossSales` are `private`—subclass `BasePlusCommissionEmployee`'s methods are not allowed to access superclass `CommissionEmployee`'s `private` instance variables. We used red text in Fig. 9.8 to indicate erroneous code. The compiler issues additional errors at lines 49–51 of `BasePlusCommissionEmployee`'s `toString` method for the same reason. The errors in `BasePlusCommissionEmployee` could have been prevented by using the *get* methods inherited from class `CommissionEmployee`. For example, line 39 could have used `getCommissionRate` and `getGrossSales` to access `CommissionEmployee`'s `private` instance variables `commissionRate` and `grossSales`, respectively. Lines 49–51 also could have used appropriate *get* methods to retrieve the values of the superclass's instance variables.

## 9.4.4 CommissionEmployee–BasePlusCommissionEmployee Inheritance Hierarchy Using protected Instance Variables

To enable class `BasePlusCommissionEmployee` to directly access superclass instance variables `firstName`, `lastName`, `socialSecurityNumber`, `grossSales` and `commissionRate`, we can declare those members as `protected` in the superclass. As we discussed in Section 9.3, a superclass's `protected` members are accessible by all subclasses of that superclass. In the new `CommissionEmployee` class, we modified only lines 6–10 of Fig. 9.4 to declare the instance variables with the `protected` access modifier as follows:

```

protected String firstName;
protected String lastName;
protected String socialSecurityNumber;
protected double grossSales; // gross weekly sales
protected double commissionRate; // commission percentage

```

The rest of the class declaration (which is not shown here) is identical to that of Fig. 9.4.

We could have declared `CommissionEmployee`'s instance variables `public` to enable subclass `BasePlusCommissionEmployee` to access them. However, declaring `public` instance variables is poor software engineering because it allows unrestricted access to these variables, greatly increasing the chance of errors. With `protected` instance variables, the subclass gets access to the instance variables, but classes that are not subclasses and classes that are not in the same package cannot access these variables directly—recall that `protected` class members are also visible to other classes in the same package.

### Class `BasePlusCommissionEmployee`

Class `BasePlusCommissionEmployee` (Fig. 9.9) extends the new version of class `CommissionEmployee` with `protected` instance variables. `BasePlusCommissionEmployee` objects inherit `CommissionEmployee`'s `protected` instance variables `firstName`, `lastName`, `socialSecurityNumber`, `grossSales` and `commissionRate`—all these variables are now `protected` members of `BasePlusCommissionEmployee`. As a result, the compiler does not generate errors when compiling line 37 of method `earnings` and lines 46–48 of method `toString`. If another class extends this version of class `BasePlusCommissionEmployee`, the new subclass also can access the `protected` members.

When you create a `BasePlusCommissionEmployee` object, it contains all instance variables declared in the class hierarchy to that point—i.e., those from classes `Object`, `CommissionEmployee` and `BasePlusCommissionEmployee`. Class `BasePlusCommissionEmployee` does not inherit class `CommissionEmployee`'s constructor. However, class `BasePlusCommissionEmployee`'s six-argument constructor (lines 10–15) calls class `CommissionEmployee`'s five-argument constructor *explicitly* to initialize the instance variables that `BasePlusCommissionEmployee` inherited from class `CommissionEmployee`. Similarly, class `CommissionEmployee`'s constructor *implicitly* calls class `Object`'s constructor. `BasePlusCommissionEmployee`'s constructor must do this *explicitly* because `CommissionEmployee` does *not* provide a no-argument constructor that could be invoked implicitly.

---

```

2 // BasePlusCommissionEmployee inherits protected instance
3 // variables from CommissionEmployee.
4
5 public class BasePlusCommissionEmployee extends CommissionEmployee
6 {
7     private double baseSalary; // base salary per week
8
9     // six-argument constructor
10    public BasePlusCommissionEmployee( String first, String last,
11        String ssn, double sales, double rate, double salary )
12    {

```

---

**Fig. 9.9** | `BasePlusCommissionEmployee` inherits `protected` instance variables from `CommissionEmployee`. (Part 1 of 2.)

```

13     super( first, last, ssn, sales, rate );
14     setBaseSalary( salary ); // validate and store base salary
15 } // end six-argument BasePlusCommissionEmployee constructor
16
17 // set base salary
18 public void setBaseSalary( double salary )
19 {
20     if ( salary >= 0.0 )
21         baseSalary = salary;
22     else
23         throw new IllegalArgumentException(
24             "Base salary must be >= 0.0" );
25 } // end method setBaseSalary
26
27 // return base salary
28 public double getBaseSalary()
29 {
30     return baseSalary;
31 } // end method getBaseSalary
32
33 // calculate earnings
34 @Override // indicates that this method overrides a superclass method
35 public double earnings()
36 {
37     return baseSalary + ( commissionRate * grossSales );
38 } // end method earnings
39
40 // return String representation of BasePlusCommissionEmployee
41 @Override // indicates that this method overrides a superclass method
42 public String toString()
43 {
44     return String.format(
45         "%s: %s %s\n%s: %s\n%s: %.2f\n%s: %.2f\n%s: %.2f",
46         "base-salaried commission employee", firstName, lastName,
47         "social security number", socialSecurityNumber,
48         "gross sales", grossSales, "commission rate", commissionRate,
49         "base salary", baseSalary );
50 } // end method toString
51 } // end class BasePlusCommissionEmployee

```

**Fig. 9.9** | BasePlusCommissionEmployee inherits protected instance variables from CommissionEmployee. (Part 2 of 2.)

### Testing Class BasePlusCommissionEmployee

The BasePlusCommissionEmployeeTest class for this example is identical to that of Fig. 9.7 and produces the same output, so we do not show it here. Although the version of class BasePlusCommissionEmployee in Fig. 9.6 does not use inheritance and the version in Fig. 9.9 does, *both classes provide the same functionality*. The source code in Fig. 9.9 (47 lines) is considerably shorter than that in Fig. 9.6 (116 lines), because most of BasePlusCommissionEmployee's functionality is now inherited from CommissionEmployee—there's now only one copy of the CommissionEmployee functionality. This makes the code easier to maintain, modify and debug, because the code related to a commission employee exists only in class CommissionEmployee.

*Notes on Using protected Instance Variables*

In this example, we declared superclass instance variables as `protected` so that subclasses could access them. Inheriting `protected` instance variables slightly increases performance, because we can directly access the variables in the subclass without incurring the overhead of a `set` or `get` method call. In most cases, however, it's better to use `private` instance variables to encourage proper software engineering, and leave code optimization issues to the compiler. Your code will be easier to maintain, modify and debug.

Using `protected` instance variables creates several potential problems. First, the subclass object can set an inherited variable's value directly without using a `set` method. Therefore, a subclass object can assign an invalid value to the variable, possibly leaving the object in an inconsistent state. For example, if we were to declare `CommissionEmployee`'s instance variable `grossSales` as `protected`, a subclass object (e.g., `BasePlusCommissionEmployee`) could then assign a negative value to `grossSales`. Another problem with using `protected` instance variables is that subclass methods are more likely to be written so that they depend on the superclass's data implementation. In practice, subclasses should depend only on the superclass services (i.e., non-`private` methods) and not on the superclass data implementation. With `protected` instance variables in the superclass, we may need to modify all the subclasses of the superclass if the superclass implementation changes. For example, if for some reason we were to change the names of instance variables `firstName` and `lastName` to `first` and `last`, then we would have to do so for all occurrences in which a subclass directly references superclass instance variables `firstName` and `lastName`. In such a case, the software is said to be **fragile** or **brittle**, because a small change in the superclass can “break” subclass implementation. You should be able to change the superclass implementation while still providing the same services to the subclasses. Of course, if the superclass services change, we must reimplement our subclasses. A third problem is that a class's `protected` members are visible to all classes in the same package as the class containing the `protected` members—this is not always desirable.

**Software Engineering Observation 9.4**

*Use the `protected` access modifier when a superclass should provide a method only to its subclasses and other classes in the same package, but not to other clients.*

**Software Engineering Observation 9.5**

*Declaring superclass instance variables `private` (as opposed to `protected`) enables the superclass implementation of these instance variables to change without affecting subclass implementations.*

**Error-Prevention Tip 9.2**

*When possible, do not include `protected` instance variables in a superclass. Instead, include non-`private` methods that access `private` instance variables. This will help ensure that objects of the class maintain consistent states.*

### 9.4.5 `CommissionEmployee`–`BasePlusCommissionEmployee` Inheritance Hierarchy Using `private` Instance Variables

Let's reexamine our hierarchy once more, this time using good software engineering practices. Class `CommissionEmployee` (Fig. 9.10) declares instance variables `firstName`, `lastName`,

socialSecurityNumber, grossSales and commissionRate as *private* (lines 6–10) and provides public methods setFirstName, getFirstName, setLastName, getLastName, setSocialSecurityNumber, getSocialSecurityNumber, setGrossSales, getGrossSales, setCommissionRate, getCommissionRate, earnings and toString for manipulating these values. Methods earnings (lines 93–96) and toString (lines 99–107) use the class's *get* methods to obtain the values of its instance variables. If we decide to change the instance-variable names, the earnings and toString declarations will not require modification—only the bodies of the *get* and *set* methods that directly manipulate the instance variables will need to change. These changes occur solely within the superclass—no changes to the subclass are needed. *Localizing the effects of changes* like this is a good software engineering practice.

---

```

94 {
95     return getCommissionRate() * getGrossSales();
96 } // end method earnings
97
98 // return String representation of CommissionEmployee object
99 @Override // indicates that this method overrides a superclass method
100 public String toString()
101 {
102     return String.format( "%s: %s %s\n%s: %s\n%s: %.2f\n%s: %.2f",
103         "commission employee", getFirstName(), getLastName(),
104         "social security number", getSocialSecurityNumber(),
105         "gross sales", getGrossSales(),
106         "commission rate", getCommissionRate() );
107 } // end method toString
108 } // end class CommissionEmployee

```

---

**Fig. 9.10** | CommissionEmployee class uses methods to manipulate its private instance variables. (Part 3 of 3.)

Subclass BasePlusCommissionEmployee (Fig. 9.11) inherits CommissionEmployee's non-private methods and can access the private superclass members via those methods. Class BasePlusCommissionEmployee has several changes that distinguish it from Fig. 9.9. Methods earnings (lines 35–39) and toString (lines 42–47) each invoke method getBaseSalary to obtain the base salary value, rather than accessing baseSalary directly. If we decide to rename instance variable baseSalary, only the bodies of method setBaseSalary and getBaseSalary will need to change.

39 } // end method earnings
40
41 // return String representation of BasePlusCommissionEmployee
42 @Override // indicates that this method overrides a superclass method
43 public String toString()
44 {
45     return String.format( "%s %s\n%s: %.2f", "base-salaried",
46         super.toString(), "base salary", getBaseSalary() );
47 } // end method toString
48 } // end class BasePlusCommissionEmployee

```

**Fig. 9.11** | BasePlusCommissionEmployee class inherits from CommissionEmployee and accesses the superclass’s private data via inherited public methods. (Part 2 of 2.)

### *Class BasePlusCommissionEmployee’s earnings Method*

Method `earnings` (lines 35–39) overrides class `CommissionEmployee`’s `earnings` method (Fig. 9.10, lines 93–96) to calculate a base-salaried commission employee’s earnings. The new version obtains the portion of the earnings based on commission alone by calling `CommissionEmployee`’s `earnings` method with `super.earnings()` (line 34), then adds the base salary to this value to calculate the total earnings. Note the syntax used to invoke an overridden superclass method from a subclass—place the keyword `super` and a dot (`.`) separator before the superclass method name. This method invocation is a good software engineering practice—if a method performs all or some of the actions needed by another method, call that method rather than duplicate its code. By having `BasePlusCommissionEmployee`’s `earnings` method invoke `CommissionEmployee`’s `earnings` method to calculate part of a `BasePlusCommissionEmployee` object’s earnings, we *avoid duplicating the code* and *reduce code-maintenance problems*. If we did not use “`super.`” then `BasePlusCommissionEmployee`’s `earnings` method would *call itself* rather than the superclass version. This would result in a phenomenon we study in Chapter 18 called *infinite recursion*, which would eventually cause the method-call stack to overflow—a fatal runtime error.

### *Class BasePlusCommissionEmployee's toString Method*

Similarly, `BasePlusCommissionEmployee`'s `toString` method (Fig. 9.11, lines 38–43) overrides class `CommissionEmployee`'s `toString` method (Fig. 9.10, lines 91–99) to return a `String` representation that's appropriate for a base-salaried commission employee. The new version creates part of a `BasePlusCommissionEmployee` object's `String` representation (i.e., the `String` "commission employee" and the values of class `CommissionEmployee`'s private instance variables) by calling `CommissionEmployee`'s `toString` method with the expression `super.toString()` (Fig. 9.11, line 42). `BasePlusCommissionEmployee`'s `toString` method then outputs the remainder of a `BasePlusCommissionEmployee` object's `String` representation (i.e., the value of class `BasePlusCommissionEmployee`'s base salary).

### **Common Programming Error 9.3**

*When a superclass method is overridden in a subclass, the subclass version often calls the superclass version to do a portion of the work. Failure to prefix the superclass method name with the keyword `super` and a dot (`.`) separator when calling the superclass's method causes the subclass method to call itself, potentially creating an error called infinite recursion. Recursion, used correctly, is a powerful capability discussed in Chapter 18.*

### *Testing Class BasePlusCommissionEmployee*

Class `BasePlusCommissionEmployeeTest` performs the same manipulations on a `BasePlusCommissionEmployee` object as in Fig. 9.7 and produces the same output, so we do not show it here. Although each `BasePlusCommissionEmployee` class you've seen behaves identically, the version in Fig. 9.11 is the best engineered. By using inheritance and by calling methods that hide the data and ensure consistency, we've efficiently and effectively constructed a well-engineered class.

### *Summary of the Inheritance Examples in Sections 9.4.1–9.4.5*

You've now seen a set of examples that were designed to teach good software engineering with inheritance. You used the keyword `extends` to create a subclass using inheritance, used protected superclass members to enable a subclass to access inherited superclass instance variables, and overrode superclass methods to provide versions that are more appropriate for subclass objects. In addition, you applied software engineering techniques from Chapter 8 and this chapter to create classes that are easy to maintain, modify and debug.

## **9.5 Constructors in Subclasses**

As we explained in the preceding section, instantiating a subclass object begins a chain of constructor calls in which the subclass constructor, before performing its own tasks, invokes its direct superclass's constructor either explicitly via the `super` reference or implicitly calling the superclass's default constructor or no-argument constructor. Similarly, if the superclass is derived from another class—as is, of course, every class except `Object`—the superclass constructor invokes the constructor of the next class up the hierarchy, and so on. The last constructor called in the chain is *always* the constructor for class `Object`. The original subclass constructor's body finishes executing *last*. Each superclass's constructor manipulates the superclass instance variables that the subclass object inherits. For example, consider again the `CommissionEmployee`–`BasePlusCommissionEmployee` hierarchy from Fig. 9.10 and Fig. 9.11. When a program creates a `BasePlusCommissionEmployee` object, its constructor is called. That constructor calls `CommissionEmployee`'s constructor,

which in turn calls `Object`'s constructor. Class `Object`'s constructor has an empty body, so it immediately returns control to `CommissionEmployee`'s constructor, which then initializes the `CommissionEmployee` private instance variables that are part of the `BasePlusCommissionEmployee` object. When `CommissionEmployee`'s constructor completes execution, it returns control to `BasePlusCommissionEmployee`'s constructor, which initializes the `BasePlusCommissionEmployee` object's `baseSalary`.

### Software Engineering Observation 9.6

*Java ensures that even if a constructor does not assign a value to an instance variable, the variable is still initialized to its default value (e.g., 0 for primitive numeric types, false for booleans, null for references).*

## 9.6 Software Engineering with Inheritance

When you extend a class, the new class inherits the superclass's members—though the private superclass members are *hidden* in the new class. You can *customize* the new class to meet your needs by *including additional members* and by *overriding* superclass members. Doing this does not require the subclass programmer to change (or even have access to) the superclass's source code. Java simply requires access to the superclass's `.class` file so it can compile and execute any program that uses or extends the superclass. This powerful capability is attractive to independent software vendors (ISVs), who can develop proprietary classes for sale or license and make them available to users in bytecode format. Users then can derive new classes from these library classes rapidly and without accessing the ISVs' proprietary source code.

### Software Engineering Observation 9.7

*Although inheriting from a class does not require access to the class's source code, developers often insist on seeing the source code to understand how the class is implemented. Developers in industry want to ensure that they're extending a solid class—for example, a class that performs well and is implemented robustly and securely.*

It's sometimes difficult to appreciate the scope of the problems faced by designers who work on large-scale software projects. People experienced with such projects say that effective software reuse improves the software-development process. Object-oriented programming facilitates software reuse, often significantly shortening development time.

The availability of substantial and useful class libraries delivers the maximum benefits of software reuse through inheritance. The standard Java class libraries that are shipped with Java tend to be rather general purpose, encouraging broad software reuse. Many other class libraries exist.

Reading subclass declarations can be confusing, because inherited members are not declared explicitly in the subclasses but are nevertheless present in them. A similar problem exists in documenting subclass members.

### Software Engineering Observation 9.8

*At the design stage in an object-oriented system, you'll often find that certain classes are closely related. You should "factor out" common instance variables and methods and place them in a superclass. Then use inheritance to develop subclasses, specializing them with capabilities beyond those inherited from the superclass.*

### Software Engineering Observation 9.9

*Declaring a subclass does not affect its superclass's source code. Inheritance preserves the integrity of the superclass.*

### Software Engineering Observation 9.10

*Designers of object-oriented systems should avoid class proliferation. Such proliferation creates management problems and can hinder software reusability, because in a huge class library it becomes difficult to locate the most appropriate classes. The alternative is to create fewer classes that provide more substantial functionality, but such classes might prove cumbersome.*

## 9.7 Class Object

As we discussed earlier in this chapter, all classes in Java inherit directly or indirectly from the `Object` class (package `java.lang`), so its 11 methods (some are overloaded) are inherited by all other classes. Figure 9.12 summarizes `Object`'s methods. We discuss several `Object` methods throughout this book (as indicated in Fig. 9.12).

| Method                | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>clone</code>    | This protected method, which takes no arguments and returns an <code>Object</code> reference, makes a copy of the object on which it's called. The default implementation performs a so-called <b>shallow copy</b> —instance-variable values in one object are copied into another object of the same type. For reference types, only the references are copied. A typical overridden <code>clone</code> method's implementation would perform a <b>deep copy</b> that creates a new object for each reference-type instance variable. Implementing <code>clone</code> correctly is difficult. For this reason, its use is discouraged. Many industry experts suggest that object serialization should be used instead. We discuss object serialization in Chapter 17, Files, Streams and Object Serialization.                                                                                                                                                                                                                  |
| <code>equals</code>   | This method compares two objects for equality and returns <code>true</code> if they're equal and <code>false</code> otherwise. The method takes any <code>Object</code> as an argument. When objects of a particular class must be compared for equality, the class should override method <code>equals</code> to compare the <i>contents</i> of the two objects. For the requirements of implementing this method, refer to the method's documentation at <a href="http://download.oracle.com/javase/6/docs/api/java/lang/Object.html#equals(java.lang.Object)">download.oracle.com/javase/6/docs/api/java/lang/Object.html#equals(java.lang.Object)</a> . The default <code>equals</code> implementation uses operator <code>==</code> to determine whether two references <i>refer to the same object</i> in memory. Section 16.3.3 demonstrates class <code>String</code> 's <code>equals</code> method and differentiates between comparing <code>String</code> objects with <code>==</code> and with <code>equals</code> . |
| <code>finalize</code> | This protected method (introduced in Section 8.10) is called by the garbage collector to perform termination housekeeping on an object just before the garbage collector reclaims the object's memory. Recall that it's unclear whether, or when, method <code>finalize</code> will be called. For this reason, most programmers should avoid method <code>finalize</code> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

**Fig. 9.12** | Object methods. (Part 1 of 2.)

| Method                                                              | Description                                                                                                                                                                                                                                                                                                                                             |
|---------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>getClass</code>                                               | Every object in Java knows its own type at execution time. Method <code>getClass</code> (used in Sections 10.5, 14.5 and 24.3) returns an object of class <code>Class</code> (package <code>java.lang</code> ) that contains information about the object's type, such as its class name (returned by <code>Class</code> method <code>getName</code> ). |
| <code>hashCode</code>                                               | Hashcodes are <code>int</code> values that are useful for high-speed storage and retrieval of information stored in a data structure that's known as a hashtable (discussed in Section 20.11). This method is also called as part of class <code>Object</code> 's default <code>toString</code> method implementation.                                  |
| <code>wait</code> , <code>notify</code> ,<br><code>notifyAll</code> | Methods <code>notify</code> , <code>notifyAll</code> and the three overloaded versions of <code>wait</code> are related to multithreading, which is discussed in Chapter 26.                                                                                                                                                                            |
| <code>toString</code>                                               | This method (introduced in Section 9.4.1) returns a <code>String</code> representation of an object. The default implementation of this method returns the package name and class name of the object's class followed by a hexadecimal representation of the value returned by the object's <code>hashCode</code> method.                               |

**Fig. 9.12** | Object methods. (Part 2 of 2.)

Recall from Chapter 7 that arrays are objects. As a result, like all other objects, arrays inherit the members of class `Object`. Every array has an overridden `clone` method that copies the array. However, if the array stores references to objects, the objects are not copied—a *shallow copy* is performed.

## 9.8 (Optional) GUI and Graphics Case Study: Displaying Text and Images Using Labels

Programs often use labels when they need to display information or instructions to the user in a graphical user interface. **Labels** are a convenient way of identifying GUI components on the screen and keeping the user informed about the current state of the program. In Java, an object of class `JLabel` (from package `javax.swing`) can display text, an image or both. The example in Fig. 9.13 demonstrates several `JLabel` features, including a plain text label, an image label and a label with both text and an image.

Lines 3–6 import the classes we need to display `JLabels`. `BorderLayout` from package `java.awt` contains constants that specify where we can place GUI components in the `JFrame`. Class `ImageIcon` represents an image that can be displayed on a `JLabel`, and class `JFrame` represents the window that will contain all the labels.

```

1 // Fig 9.13: LabelDemo.java
2 // Demonstrates the use of labels.
3 import java.awt.BorderLayout;
4 import javax.swing.ImageIcon;
5 import javax.swing.JLabel;
6 import javax.swing.JFrame;
7

```

**Fig. 9.13** | `JLabel` with text and with images. (Part 1 of 2.)

```

8 public class LabelDemo
9 {
10     public static void main( String[] args )
11     {
12         // Create a label with plain text
13         JLabel northLabel = new JLabel( "North" );
14
15         // create an icon from an image so we can put it on a JLabel
16         ImageIcon labelIcon = new ImageIcon( "GUItip.gif" );
17
18         // create a label with an Icon instead of text
19         JLabel centerLabel = new JLabel( labelIcon );
20
21         // create another label with an Icon
22         JLabel southLabel = new JLabel( labelIcon );
23
24         // set the label to display text (as well as an icon)
25         southLabel.setText( "South" );
26
27         // create a frame to hold the labels
28         JFrame application = new JFrame();
29
30         application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
31
32         // add the labels to the frame; the second argument specifies
33         // where on the frame to add the label
34         application.add( northLabel, BorderLayout.NORTH );
35         application.add( centerLabel, BorderLayout.CENTER );
36         application.add( southLabel, BorderLayout.SOUTH );
37
38         application.setSize( 300, 300 ); // set the size of the frame
39         application.setVisible( true ); // show the frame
40     } // end main
41 } // end class LabelDemo

```

**Fig. 9.13** | JLabel with text and with images. (Part 2 of 2.)

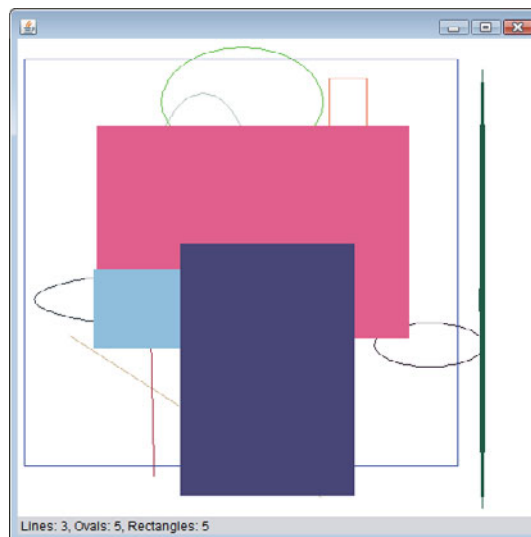

Line 13 creates a JLabel that displays its constructor argument—the string "North". Line 16 declares local variable labelIcon and assigns it a new ImageIcon. The constructor

for `ImageIcon` receives a `String` that specifies the path to the image. Since we specify only a file name, Java assumes that it's in the same directory as class `LabelDemo`. `ImageIcon` can load images in GIF, JPEG and PNG image formats. Line 19 declares and initializes local variable `centerLabel` with a `JLabel` that displays the `LabelIcon`. Line 22 declares and initializes local variable `southLabel` with a `JLabel` similar to the one in line 19. However, line 25 calls method `setText` to change the text the label displays. Method `setText` can be called on any `JLabel` to change its text. This `JLabel` displays both the icon and the text.

Line 28 creates the `JFrame` that displays the `JLabels`, and line 30 indicates that the program should terminate when the `JFrame` is closed. We attach the labels to the `JFrame` in lines 34–36 by calling an overloaded version of method `add` that takes two parameters. The first parameter is the component we want to attach, and the second is the region in which it should be placed. Each `JFrame` has an associated **layout** that helps the `JFrame` position the GUI components that are attached to it. The default layout for a `JFrame` is known as a **BorderLayout** and has five regions—NORTH (top), SOUTH (bottom), EAST (right side), WEST (left side) and CENTER. Each of these is declared as a constant in class `BorderLayout`. When calling method `add` with one argument, the `JFrame` places the component in the CENTER automatically. If a position already contains a component, then the new component takes its place. Lines 38 and 39 set the size of the `JFrame` and make it visible on screen.

### *GUI and Graphics Case Study Exercise*

**9.1** Modify GUI and Graphics Case Study Exercise 8.1 to include a `JLabel` as a status bar that displays counts representing the number of each shape displayed. Class `DrawPanel` should declare a method that returns a `String` containing the status text. In `main`, first create the `DrawPanel`, then create the `JLabel` with the status text as an argument to the `JLabel`'s constructor. Attach the `JLabel` to the SOUTH region of the `JFrame`, as shown in Fig. 9.14.

**Fig. 9.14** | `JLabel` displaying shape statistics.

## 9.9 Wrap-Up

This chapter introduced inheritance—the ability to create classes by absorbing an existing class’s members and embellishing them with new capabilities. You learned the notions of superclasses and subclasses and used keyword `extends` to create a subclass that inherits members from a superclass. We showed how to use the `@Override` annotation to prevent unintended overloading by indicating that a method overrides a superclass method. We introduced the access modifier `protected`; subclass methods can directly access `protected` superclass members. You learned how to use `super` to access overridden superclass members. You also saw how constructors are used in inheritance hierarchies. Finally, you learned about the methods of class `Object`, the direct or indirect superclass of all Java classes.

In Chapter 10, *Object-Oriented Programming: Polymorphism*, we build on our discussion of inheritance by introducing polymorphism—an object-oriented concept that enables us to write programs that conveniently handle, in a more general manner, objects of a wide variety of classes related by inheritance. After studying Chapter 10, you’ll be familiar with classes, objects, encapsulation, inheritance and polymorphism—the key technologies of object-oriented programming.

### Summary

#### *Section 9.1 Introduction*

- Inheritance (p. 360) reduces program-development time.
- The direct superclass (p. 360) of a subclass (specified by the keyword `extends` in the first line of a class declaration) is the superclass from which the subclass inherits. An indirect superclass (p. 360) of a subclass is two or more levels up the class hierarchy from that subclass.
- In single inheritance (p. 360), a class is derived from one direct superclass. In multiple inheritance, a class is derived from more than one direct superclass. Java does not support multiple inheritance.
- A subclass is more specific than its superclass and represents a smaller group of objects (p. 360).
- Every object of a subclass is also an object of that class’s superclass. However, a superclass object is not an object of its class’s subclasses.
- An *is-a* relationship (p. 361) represents inheritance. In an *is-a* relationship, an object of a subclass also can be treated as an object of its superclass.
- A *has-a* relationship (p. 361) represents composition. In a *has-a* relationship, a class object contains references to objects of other classes.

#### *Section 9.2 Superclasses and Subclasses*

- Single-inheritance relationships form treelike hierarchical structures—a superclass exists in a hierarchical relationship with its subclasses.

#### *Section 9.3 protected Members*

- A superclass’s `public` members are accessible wherever the program has a reference to an object of that superclass or one of its subclasses.
- A superclass’s `private` members can be accessed directly only within the superclass’s declaration.
- A superclass’s `protected` members (p. 363) have an intermediate level of protection between `public` and `private` access. They can be accessed by members of the superclass, by members of its subclasses and by members of other classes in the same package.

- A superclass's private members are hidden in its subclasses and can be accessed only through the `public` or protected methods inherited from the superclass.
- An overridden superclass method can be accessed from a subclass if the superclass method name is preceded by `super` (p. 363) and a dot (`.`) separator.

#### Section 9.4 Relationship between Superclasses and Subclasses

- A subclass cannot access the private members of its superclass, but it can access the non-private members.
- A subclass can invoke a constructor of its superclass by using the keyword `super`, followed by a set of parentheses containing the superclass constructor arguments. This must appear as the first statement in the subclass constructor's body.
- A superclass method can be overridden in a subclass to declare an appropriate implementation for the subclass.
- The annotation `@Override` (p. 368) indicates that a method should override a superclass method. When the compiler encounters a method declared with `@Override`, it compares the method's signature with the superclass's method signatures. If there isn't an exact match, the compiler issues an error message, such as "method does not override or implement a method from a supertype."
- Method `toString` takes no arguments and returns a `String`. The `Object` class's `toString` method is normally overridden by a subclass.
- When an object is output using the `%s` format specifier, the object's `toString` method is called implicitly to obtain its `String` representation.

#### Section 9.5 Constructors in Subclasses

- The first task of a subclass constructor is to call its direct superclass's constructor (p. 377) to ensure that the instance variables inherited from the superclass are initialized.

#### Section 9.6 Software Engineering with Inheritance

- Declaring instance variables `private`, while providing non-private methods to manipulate and perform validation, helps enforce good software engineering.

#### Section 9.7 Object Class

- See the table of class `Object`'s methods in Fig. 9.12.

### Self-Review Exercises

- 9.1 Fill in the blanks in each of the following statements:
- \_\_\_\_\_ is a form of software reusability in which new classes acquire the members of existing classes and embellish those classes with new capabilities.
  - A superclass's \_\_\_\_\_ members can be accessed in the superclass declaration *and in* subclass declarations.
  - In a(n) \_\_\_\_\_ relationship, an object of a subclass can also be treated as an object of its superclass.
  - In a(n) \_\_\_\_\_ relationship, a class object has references to objects of other classes as members.
  - In single inheritance, a class exists in a(n) \_\_\_\_\_ relationship with its subclasses.
  - A superclass's \_\_\_\_\_ members are accessible anywhere that the program has a reference to an object of that superclass or to an object of one of its subclasses.
  - When an object of a subclass is instantiated, a superclass \_\_\_\_\_ is called implicitly or explicitly.

h) Subclass constructors can call superclass constructors via the \_\_\_\_\_ keyword.

- 9.2** State whether each of the following is *true* or *false*. If a statement is *false*, explain why.
- Superclass constructors are not inherited by subclasses.
  - A *has-a* relationship is implemented via inheritance.
  - A Car class has an *is-a* relationship with the SteeringWheel and Brakes classes.
  - When a subclass redefines a superclass method by using the same signature, the subclass is said to overload that superclass method.

## Answers to Self-Review Exercises

**9.1** a) Inheritance. b) `public` and `protected`. c) *is-a* or inheritance. d) *has-a* or composition. e) hierarchical. f) `public`. g) constructor. h) `super`.

**9.2** a) True. b) False. A *has-a* relationship is implemented via composition. An *is-a* relationship is implemented via inheritance. c) False. This is an example of a *has-a* relationship. Class Car has an *is-a* relationship with class Vehicle. d) False. This is known as overriding, not overloading—an overloaded method has the same name, but a different signature.

## Exercises

**9.3** Many programs written with inheritance could be written with composition instead, and vice versa. Rewrite class `BasePlusCommissionEmployee` (Fig. 9.11) of the `CommissionEmployee–BasePlusCommissionEmployee` hierarchy to use composition rather than inheritance.

**9.4** Discuss the ways in which inheritance promotes software reuse, saves time during program development and helps prevent errors.

**9.5** Draw an inheritance hierarchy for students at a university similar to the hierarchy shown in Fig. 9.2. Use `Student` as the superclass of the hierarchy, then extend `Student` with classes `UndergraduateStudent` and `GraduateStudent`. Continue to extend the hierarchy as deep (i.e., as many levels) as possible. For example, `Freshman`, `Sophomore`, `Junior` and `Senior` might extend `UndergraduateStudent`, and `DoctoralStudent` and `MastersStudent` might be subclasses of `GraduateStudent`. After drawing the hierarchy, discuss the relationships that exist between the classes. [Note: You do not need to write any code for this exercise.]

**9.6** The world of shapes is much richer than the shapes included in the inheritance hierarchy of Fig. 9.3. Write down all the shapes you can think of—both two-dimensional and three-dimensional—and form them into a more complete `Shape` hierarchy with as many levels as possible. Your hierarchy should have class `Shape` at the top. Classes `TwoDimensionalShape` and `ThreeDimensionalShape` should extend `Shape`. Add additional subclasses, such as `Quadrilateral` and `Sphere`, at their correct locations in the hierarchy as necessary.

**9.7** Some programmers prefer not to use `protected` access, because they believe it breaks the encapsulation of the superclass. Discuss the relative merits of using `protected` access vs. using `private` access in superclasses.

**9.8** Write an inheritance hierarchy for classes `Quadrilateral`, `Trapezoid`, `Parallelogram`, `Rectangle` and `Square`. Use `Quadrilateral` as the superclass of the hierarchy. Create and use a `Point` class to represent the points in each shape. Make the hierarchy as deep (i.e., as many levels) as possible. Specify the instance variables and methods for each class. The `private` instance variables of `Quadrilateral` should be the *x-y* coordinate pairs for the four endpoints of the `Quadrilateral`. Write a program that instantiates objects of your classes and outputs each object's area (except `Quadrilateral`).

## Object-Oriented Programming: Polymorphism

*One Ring to rule them all,  
One Ring to find them,  
One Ring to bring them all  
and in the darkness bind them.*

—John Ronald Reuel Tolkien

*General propositions do not  
decide concrete cases.*

—Oliver Wendell Holmes

*A philosopher of imposing  
stature doesn't think in a  
vacuum. Even his most abstract  
ideas are, to some extent,  
conditioned by what is or is not  
known in the time when he lives.*

—Alfred North Whitehead

*Why art thou cast down, O my  
soul?*

—Psalms 42:5

### Objectives

In this chapter you'll learn:

- The concept of polymorphism.
- To use overridden methods to effect polymorphism.
- To distinguish between abstract and concrete classes.
- To declare abstract methods to create abstract classes.
- How polymorphism makes systems extensible and maintainable.
- To determine an object's type at execution time.
- To declare and implement interfaces.

- 10.1 Introduction
- 10.2 Polymorphism Examples
- 10.3 Demonstrating Polymorphic Behavior
- 10.4 Abstract Classes and Methods
- 10.5 Case Study: Payroll System Using Polymorphism
  - 10.5.1 Abstract Superclass `Employee`
  - 10.5.2 Concrete Subclass `SalariedEmployee`
  - 10.5.3 Concrete Subclass `HourlyEmployee`
  - 10.5.4 Concrete Subclass `CommissionEmployee`
  - 10.5.5 Indirect Concrete Subclass `BasePlusCommissionEmployee`
  - 10.5.6 Polymorphic Processing, Operator `instanceof` and Downcasting
  - 10.5.7 Summary of the Allowed Assignments Between Superclass and Subclass Variables
- 10.6 `final` Methods and Classes
- 10.7 Case Study: Creating and Using Interfaces
  - 10.7.1 Developing a `Payable` Hierarchy
  - 10.7.2 Interface `Payable`
  - 10.7.3 Class `Invoice`
  - 10.7.4 Modifying Class `Employee` to Implement Interface `Payable`
  - 10.7.5 Modifying Class `SalariedEmployee` for Use in the `Payable` Hierarchy
  - 10.7.6 Using Interface `Payable` to Process `Invoices` and `Employees` Polymorphically
  - 10.7.7 Common Interfaces of the Java API
- 10.8 (Optional) GUI and Graphics Case Study: Drawing with Polymorphism
- 10.9 Wrap-Up

Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference

## 10.1 Introduction

We continue our study of object-oriented programming by explaining and demonstrating **polymorphism** with inheritance hierarchies. Polymorphism enables you to “program in the general” rather than “program in the specific.” In particular, polymorphism enables you to write programs that process objects that share the same superclass (either directly or indirectly) as if they’re all objects of the superclass; this can simplify programming.

Consider the following example of polymorphism. Suppose we create a program that simulates the movement of several types of animals for a biological study. Classes `Fish`, `Frog` and `Bird` represent the types of animals under investigation. Imagine that each class extends superclass `Animal`, which contains a method `move` and maintains an animal’s current location as  $x$ - $y$  coordinates. Each subclass implements method `move`. Our program maintains an `Animal` array containing references to objects of the various `Animal` subclasses. To simulate the animals’ movements, the program sends each object the *same* message once per second—namely, `move`. Each specific type of `Animal` responds to a `move` message in its own way—a `Fish` might swim three feet, a `Frog` might jump five feet and a `Bird` might fly ten feet. Each object knows how to modify its  $x$ - $y$  coordinates appropriately for its *specific* type of movement. Relying on each object to know how to “do the right thing” (i.e., do what is appropriate for that type of object) in response to the same method call is the key concept of polymorphism. The same message (in this case, `move`) sent to a variety of objects has “many forms” of results—hence the term polymorphism.

### *Implementing for Extensibility*

With polymorphism, we can design and implement systems that are easily extensible—new classes can be added with little or no modification to the general portions of the pro-

gram, as long as the new classes are part of the inheritance hierarchy that the program processes generically. The only parts of a program that must be altered are those that require direct knowledge of the new classes that we add to the hierarchy. For example, if we extend class `Animal` to create class `Tortoise` (which might respond to a move message by crawling one inch), we need to write only the `Tortoise` class and the part of the simulation that instantiates a `Tortoise` object. The portions of the simulation that tell each `Animal` to move generically can remain the same.

### Chapter Overview

First, we discuss common examples of polymorphism. We then provide a simple example demonstrating polymorphic behavior. We use superclass references to manipulate *both* superclass objects and subclass objects polymorphically.

We then present a case study that revisits the employee hierarchy of Section 9.4.5. We develop a simple payroll application that polymorphically calculates the weekly pay of several different types of employees using each employee's earnings method. Though the earnings of each type of employee are calculated in a specific way, polymorphism allows us to process the employees "in the general." In the case study, we enlarge the hierarchy to include two new classes—`SalariedEmployee` (for people paid a fixed weekly salary) and `HourlyEmployee` (for people paid an hourly salary and "time-and-a-half" for overtime). We declare a common set of functionality for all the classes in the updated hierarchy in an "abstract" class, `Employee`, from which "concrete" classes `SalariedEmployee`, `HourlyEmployee` and `CommissionEmployee` inherit directly and "concrete" class `BasePlusCommissionEmployee` inherits indirectly. As you'll soon see, *when we invoke each employee's earnings method off a superclass Employee reference, the correct earnings subclass calculation is performed*, due to Java's polymorphic capabilities.

### Programming in the Specific

Occasionally, when performing polymorphic processing, we need to program "in the specific." Our `Employee` case study demonstrates that a program can determine the type of an object at *execution time* and act on that object accordingly. In the case study, we've decided that `BasePlusCommissionEmployee`s should receive 10% raises on their base salaries. So, we use these capabilities to determine whether a particular employee object *is a* `BasePlusCommissionEmployee`. If so, we increase that employee's base salary by 10%.

### Interfaces

The chapter continues with an introduction to Java interfaces. An interface describes a set of methods that can be called on an object, but does *not* provide concrete implementations for all the methods. You can declare classes that **implement** (i.e., provide concrete implementations for the methods of) one or more interfaces. Each interface method must be declared in all the classes that explicitly implement the interface. Once a class implements an interface, all objects of that class have an *is-a* relationship with the interface type, and all objects of the class are guaranteed to provide the functionality described by the interface. This is true of all subclasses of that class as well.

Interfaces are particularly useful for assigning common functionality to possibly *unrelated* classes. This allows objects of unrelated classes to be processed polymorphically—objects of classes that implement the same interface can respond to all of the interface

method calls. To demonstrate creating and using interfaces, we modify our payroll application to create a general accounts payable application that can calculate payments due for company employees and invoice amounts to be billed for purchased goods. As you'll see, interfaces enable polymorphic capabilities similar to those possible with inheritance.

## 10.2 Polymorphism Examples

We now consider several additional examples of polymorphism.

### *Quadrilaterals*

If class `Rectangle` is derived from class `Quadrilateral`, then a `Rectangle` object is a more specific version of a `Quadrilateral`. Any operation (e.g., calculating the perimeter or the area) that can be performed on a `Quadrilateral` can also be performed on a `Rectangle`. These operations can also be performed on other `Quadrilaterals`, such as `Squares`, `Parallelograms` and `Trapezoids`. The polymorphism occurs when a program invokes a method through a superclass `Quadrilateral` variable—at execution time, the correct subclass version of the method is called, based on the type of the reference stored in the superclass variable. You'll see a simple code example that illustrates this process in Section 10.3.

### *Space Objects in a Video Game*

Suppose we design a video game that manipulates objects of classes `Martian`, `Venusian`, `Plutonian`, `SpaceShip` and `LaserBeam`. Imagine that each class inherits from the superclass `SpaceObject`, which contains method `draw`. Each subclass implements this method. A screen manager maintains a collection (e.g., a `SpaceObject` array) of references to objects of the various classes. To refresh the screen, the screen manager periodically sends each object the same message—namely, `draw`. However, each object responds its own way, based on its class. For example, a `Martian` object might draw itself in red with green eyes and the appropriate number of antennae. A `SpaceShip` object might draw itself as a bright silver flying saucer. A `LaserBeam` object might draw itself as a bright red beam across the screen. Again, the *same* message (in this case, `draw`) sent to a variety of objects has “many forms” of results.

A screen manager might use polymorphism to facilitate adding new classes to a system with minimal modifications to the system's code. Suppose that we want to add `Mercurian` objects to our video game. To do so, we'd build a class `Mercurian` that extends `SpaceObject` and provides its own `draw` method implementation. When `Mercurian` objects appear in the `SpaceObject` collection, the screen manager code *invokes method `draw`, exactly as it does for every other object in the collection, regardless of its type*. So the new `Mercurian` objects simply “plug right in” without any modification of the screen manager code by the programmer. Thus, without modifying the system (other than to build new classes and modify the code that creates new objects), you can use polymorphism to conveniently include additional types that were not envisioned when the system was created.

### Software Engineering Observation 10.1

*Polymorphism enables you to deal in generalities and let the execution-time environment handle the specifics. You can command objects to behave in manners appropriate to those objects, without knowing their types (as long as the objects belong to the same inheritance hierarchy).*

### Software Engineering Observation 10.2

*Polymorphism promotes extensibility: Software that invokes polymorphic behavior is independent of the object types to which messages are sent. New object types that can respond to existing method calls can be incorporated into a system without modifying the base system. Only client code that instantiates new objects must be modified to accommodate new types.*

## 10.3 Demonstrating Polymorphic Behavior

Section 9.4 created a class hierarchy, in which class `BasePlusCommissionEmployee` inherited from `CommissionEmployee`. The examples in that section manipulated `CommissionEmployee` and `BasePlusCommissionEmployee` objects by using references to them to invoke their methods—we aimed superclass variables at superclass objects and subclass variables at subclass objects. These assignments are natural and straightforward—superclass variables are *intended* to refer to superclass objects, and subclass variables are *intended* to refer to subclass objects. However, as you’ll soon see, other assignments are possible.

In the next example, we aim a *superclass* reference at a *subclass* object. We then show how invoking a method on a subclass object via a superclass reference invokes the *subclass* functionality—the type of the *referenced object*, not the type of the *variable*, determines which method is called. This example demonstrates that *an object of a subclass can be treated as an object of its superclass*, enabling various interesting manipulations. A program can create an array of superclass variables that refer to objects of many subclass types. This is allowed because each subclass object *is an* object of its superclass. For instance, we can assign the reference of a `BasePlusCommissionEmployee` object to a superclass `CommissionEmployee` variable, because a `BasePlusCommissionEmployee` *is a* `CommissionEmployee`—we can treat a `BasePlusCommissionEmployee` as a `CommissionEmployee`.

As you’ll learn later in the chapter, you *cannot treat a superclass object as a subclass object*, because a superclass object is *not* an object of any of its subclasses. For example, we cannot assign the reference of a `CommissionEmployee` object to a subclass `BasePlusCommissionEmployee` variable, because a `CommissionEmployee` is *not* a `BasePlusCommissionEmployee`—a `CommissionEmployee` does *not* have a `baseSalary` instance variable and does *not* have methods `setBaseSalary` and `getBaseSalary`. The *is-a* relationship applies only *up the hierarchy* from a subclass to its direct (and indirect) superclasses, and *not vice versa* (i.e., not down the hierarchy from a superclass to its subclasses).

The Java compiler *does* allow the assignment of a superclass reference to a subclass variable if we explicitly cast the superclass reference to the subclass type—a technique we discuss in Section 10.5. Why would we ever want to perform such an assignment? A superclass reference can be used to invoke only the methods declared in the superclass—attempting to invoke subclass-only methods through a superclass reference results in compilation errors. If a program needs to perform a subclass-specific operation on a subclass object referenced by a superclass variable, the program must first cast the superclass reference to a subclass reference through a technique known as **downcasting**. This enables the program to invoke subclass methods that are not in the superclass. We show a downcasting example in Section 10.5.

The example in Fig. 10.1 demonstrates three ways to use superclass and subclass variables to store references to superclass and subclass objects. The first two are straightfor-

ward—as in Section 9.4, we assign a superclass reference to a superclass variable, and a subclass reference to a subclass variable. Then we demonstrate the relationship between subclasses and superclasses (i.e., the *is-a* relationship) by assigning a subclass reference to a superclass variable. This program uses classes `CommissionEmployee` and `BasePlusCommissionEmployee` from Fig. 9.10 and Fig. 9.11, respectively.

```

1 // Fig. 10.1: PolymorphismTest.java
2 // Assigning superclass and subclass references to superclass and
3 // subclass variables.
4
5 public class PolymorphismTest
6 {
7     public static void main( String[] args )
8     {
9         // assign superclass reference to superclass variable
10        CommissionEmployee commissionEmployee = new CommissionEmployee(
11            "Sue", "Jones", "222-22-2222", 10000, .06 );
12
13        // assign subclass reference to subclass variable
14        BasePlusCommissionEmployee basePlusCommissionEmployee =
15            new BasePlusCommissionEmployee(
16                "Bob", "Lewis", "333-33-3333", 5000, .04, 300 );
17
18        // invoke toString on superclass object using superclass variable
19        System.out.printf( "%s %s:\n\n%s\n\n",
20            "Call CommissionEmployee's toString with superclass reference ",
21            "to superclass object", commissionEmployee.toString() );
22
23        // invoke toString on subclass object using subclass variable
24        System.out.printf( "%s %s:\n\n%s\n\n",
25            "Call BasePlusCommissionEmployee's toString with subclass",
26            "reference to subclass object",
27            basePlusCommissionEmployee.toString() );
28
29        // invoke toString on subclass object using superclass variable
30        CommissionEmployee commissionEmployee2 =
31            basePlusCommissionEmployee;
32        System.out.printf( "%s %s:\n\n%s\n",
33            "Call BasePlusCommissionEmployee's toString with superclass",
34            "reference to subclass object", commissionEmployee2.toString() );
35    } // end main
36 } // end class PolymorphismTest

```

Call CommissionEmployee's toString with superclass reference to superclass object:

```

commission employee: Sue Jones
social security number: 222-22-2222
gross sales: 10000.00
commission rate: 0.06

```

**Fig. 10.1** | Assigning superclass and subclass references to superclass and subclass variables. (Part 1 of 2.)

```

Call BasePlusCommissionEmployee's toString with subclass reference to
subclass object:

base-salaried commission employee: Bob Lewis
social security number: 333-33-3333
gross sales: 5000.00
commission rate: 0.04
base salary: 300.00

Call BasePlusCommissionEmployee's toString with superclass reference to
subclass object:

base-salaried commission employee: Bob Lewis
social security number: 333-33-3333
gross sales: 5000.00
commission rate: 0.04
base salary: 300.00

```

**Fig. 10.1** | Assigning superclass and subclass references to superclass and subclass variables. (Part 2 of 2.)

In Fig. 10.1, lines 10–11 create a `CommissionEmployee` object and assign its reference to a `CommissionEmployee` variable. Lines 14–16 create a `BasePlusCommissionEmployee` object and assign its reference to a `BasePlusCommissionEmployee` variable. These assignments are natural—for example, a `CommissionEmployee` variable’s primary purpose is to hold a reference to a `CommissionEmployee` object. Lines 19–21 use `commissionEmployee` to invoke `toString` explicitly. Because `commissionEmployee` refers to a `CommissionEmployee` object, superclass `CommissionEmployee`’s version of `toString` is called. Similarly, lines 24–27 use `basePlusCommissionEmployee` to invoke `toString` explicitly on the `BasePlusCommissionEmployee` object. This invokes subclass `BasePlusCommissionEmployee`’s version of `toString`.

Lines 30–31 then assign the reference of subclass object `basePlusCommissionEmployee` to a superclass `CommissionEmployee` variable, which lines 32–34 use to invoke method `toString`. *When a superclass variable contains a reference to a subclass object, and that reference is used to call a method, the subclass version of the method is called.* Hence, `commissionEmployee2.toString()` in line 34 actually calls class `BasePlusCommissionEmployee`’s `toString` method. The Java compiler allows this “crossover” because an object of a subclass *is an* object of its superclass (but not vice versa). When the compiler encounters a method call made through a variable, the compiler determines if the method can be called by checking the variable’s class type. If that class contains the proper method declaration (or inherits one), the call is compiled. At execution time, the type of the object to which the variable refers determines the actual method to use. This process, called *dynamic binding*, is discussed in detail in Section 10.5.

## 10.4 Abstract Classes and Methods

When we think of a class, we assume that programs will create objects of that type. Sometimes it’s useful to declare classes—called **abstract classes**—for which you *never* intend to create objects. Because they’re used only as superclasses in inheritance hierarchies, we refer

to them as **abstract superclasses**. These classes cannot be used to instantiate objects, because, as we'll soon see, abstract classes are *incomplete*. Subclasses must declare the “missing pieces” to become “concrete” classes, from which you can instantiate objects. Otherwise, these subclasses, too, will be abstract. We demonstrate abstract classes in Section 10.5.

### *Purpose of Abstract Classes*

An abstract class's purpose is to provide an appropriate superclass from which other classes can inherit and thus share a common design. In the Shape hierarchy of Fig. 9.3, for example, subclasses inherit the notion of what it means to be a Shape—perhaps common attributes such as `location`, `color` and `borderThickness`, and behaviors such as `draw`, `move`, `resize` and `changeColor`. Classes that can be used to instantiate objects are called **concrete classes**. Such classes provide implementations of *every* method they declare (some of the implementations can be inherited). For example, we could derive concrete classes `Circle`, `Square` and `Triangle` from abstract superclass `TwoDimensionalShape`. Similarly, we could derive concrete classes `Sphere`, `Cube` and `Tetrahedron` from abstract superclass `ThreeDimensionalShape`. Abstract superclasses are *too general* to create real objects—they specify only what is common among subclasses. We need to be more *specific* before we can create objects. For example, if you send the `draw` message to abstract class `TwoDimensionalShape`, the class knows that two-dimensional shapes should be drawable, but it does not know what specific shape to draw, so it cannot implement a real `draw` method. Concrete classes provide the specifics that make it reasonable to instantiate objects.

Not all hierarchies contain abstract classes. However, you'll often write client code that uses only abstract superclass types to reduce the client code's dependencies on a range of subclass types. For example, you can write a method with a parameter of an abstract superclass type. When called, such a method can receive an object of any concrete class that directly or indirectly extends the superclass specified as the parameter's type.

Abstract classes sometimes constitute several levels of a hierarchy. For example, the Shape hierarchy of Fig. 9.3 begins with abstract class `Shape`. On the next level of the hierarchy are *abstract* classes `TwoDimensionalShape` and `ThreeDimensionalShape`. The next level of the hierarchy declares *concrete* classes for `TwoDimensionalShapes` (`Circle`, `Square` and `Triangle`) and for `ThreeDimensionalShapes` (`Sphere`, `Cube` and `Tetrahedron`).

### *Declaring an Abstract Class and Abstract Methods*

You make a class abstract by declaring it with keyword **abstract**. An abstract class normally contains one or more **abstract methods**. An abstract method is one with keyword `abstract` in its declaration, as in

```
public abstract void draw(); // abstract method
```

Abstract methods do *not* provide implementations. A class that contains *any* abstract methods must be explicitly declared `abstract` even if that class contains some concrete (nonabstract) methods. Each concrete subclass of an abstract superclass also must provide concrete implementations of each of the superclass's abstract methods. Constructors and static methods cannot be declared `abstract`. Constructors are not inherited, so an abstract constructor could never be implemented. Though non-private static methods are inherited, they cannot be overridden. Since abstract methods are meant to be overridden so that they can process objects based on their types, it would not make sense to declare a static method as `abstract`.

### Software Engineering Observation 10.3

*An abstract class declares common attributes and behaviors (both abstract and concrete) of the various classes in a class hierarchy. An abstract class typically contains one or more abstract methods that subclasses must override if they are to be concrete. The instance variables and concrete methods of an abstract class are subject to the normal rules of inheritance.*

### Common Programming Error 10.1

*Attempting to instantiate an object of an abstract class is a compilation error.*

### Common Programming Error 10.2

*Failure to implement a superclass's abstract methods in a subclass is a compilation error unless the subclass is also declared abstract.*

## Using Abstract Classes to Declare Variables

Although we cannot instantiate objects of abstract superclasses, you'll soon see that we *can* use abstract superclasses to declare variables that can hold references to objects of any concrete class derived from those abstract superclasses. Programs typically use such variables to manipulate subclass objects polymorphically. You also can use abstract superclass names to invoke `static` methods declared in those abstract superclasses.

Consider another application of polymorphism. A drawing program needs to display many shapes, including types of new shapes that you'll add to the system after writing the drawing program. The drawing program might need to display shapes, such as `Circles`, `Triangles`, `Rectangles` or others, that derive from abstract class `Shape`. The drawing program uses `Shape` variables to manage the objects that are displayed. To draw any object in this inheritance hierarchy, the drawing program uses a superclass `Shape` variable containing a reference to the subclass object to invoke the object's `draw` method. This method is declared abstract in superclass `Shape`, so each concrete subclass *must* implement method `draw` in a manner specific to that shape—each object in the `Shape` inheritance hierarchy *knows how to draw itself*. The drawing program does not have to worry about the type of each object or whether the program has ever encountered objects of that type.

## Layered Software Systems

Polymorphism is particularly effective for implementing so-called layered software systems. In operating systems, for example, each type of physical device could operate quite differently from the others. Even so, commands to read or write data from and to devices may have a certain uniformity. For each device, the operating system uses a piece of software called a *device driver* to control all communication between the system and the device. The write message sent to a device-driver object needs to be interpreted specifically in the context of that driver and how it manipulates devices of a specific type. However, the write call itself really is no different from the write to any other device in the system—place some number of bytes from memory onto that device. An object-oriented operating system might use an abstract superclass to provide an “interface” appropriate for all device drivers. Then, through inheritance from that abstract superclass, subclasses are formed

that all behave similarly. The device-driver methods are declared as abstract methods in the abstract superclass. The implementations of these abstract methods are provided in the concrete subclasses that correspond to the specific types of device drivers. New devices are always being developed, often long after the operating system has been released. When you buy a new device, it comes with a device driver provided by the device vendor. The device is immediately operational after you connect it to your computer and install the driver. This is another elegant example of how polymorphism makes systems *extensible*.

## 10.5 Case Study: Payroll System Using Polymorphism

This section reexamines the `CommissionEmployee-BasePlusCommissionEmployee` hierarchy that we explored throughout Section 9.4. Now we use an abstract method and polymorphism to perform payroll calculations based on an enhanced employee inheritance hierarchy that meets the following requirements:

*A company pays its employees on a weekly basis. The employees are of four types: Salaried employees are paid a fixed weekly salary regardless of the number of hours worked, hourly employees are paid by the hour and receive overtime pay (i.e., 1.5 times their hourly salary rate) for all hours worked in excess of 40 hours, commission employees are paid a percentage of their sales and base-salaried commission employees receive a base salary plus a percentage of their sales. For the current pay period, the company has decided to reward salaried-commission employees by adding 10% to their base salaries. The company wants to write an application that performs its payroll calculations polymorphically.*

We use abstract class `Employee` to represent the general concept of an employee. The classes that extend `Employee` are `SalariedEmployee`, `CommissionEmployee` and `HourlyEmployee`. Class `BasePlusCommissionEmployee`—which extends `CommissionEmployee`—represents the last employee type. The UML class diagram in Fig. 10.2 shows the inheritance hierarchy for our polymorphic employee-payroll application. Abstract class name `Employee` is italicized—a convention of the UML.

**Fig. 10.2** | `Employee` hierarchy UML class diagram.

Abstract superclass `Employee` declares the “interface” to the hierarchy—that is, the set of methods that a program can invoke on all `Employee` objects. We use the term “interface” here in a general sense to refer to the various ways programs can communicate with objects

of any `Employee` subclass. Be careful not to confuse the general notion of an “interface” with the formal notion of a Java interface, the subject of Section 10.7. Each employee, regardless of the way his or her earnings are calculated, has a first name, a last name and a social security number, so private instance variables `firstName`, `lastName` and `socialSecurityNumber` appear in abstract superclass `Employee`.

The following sections implement the `Employee` class hierarchy of Fig. 10.2. The first section implements abstract superclass `Employee`. The next four sections each implement one of the concrete classes. The last section implements a test program that builds objects of all these classes and processes those objects polymorphically.

### 10.5.1 Abstract Superclass `Employee`

Class `Employee` (Fig. 10.4) provides methods `earnings` and `toString`, in addition to the `get` and `set` methods that manipulate `Employee`’s instance variables. An `earnings` method certainly applies generically to all employees. But each earnings calculation depends on the employee’s class. So we declare `earnings` as abstract in superclass `Employee` because a default implementation does not make sense for that method—there isn’t enough information to determine what amount earnings should return. Each subclass overrides `earnings` with an appropriate implementation. To calculate an employee’s earnings, the program assigns to a superclass `Employee` variable a reference to the employee’s object, then invokes the `earnings` method on that variable. We maintain an array of `Employee` variables, each holding a reference to an `Employee` object. (Of course, there cannot be `Employee` objects, because `Employee` is an abstract class. Because of inheritance, however, all objects of all subclasses of `Employee` may nevertheless be thought of as `Employee` objects.) The program will iterate through the array and call method `earnings` for each `Employee` object. Java processes these method calls polymorphically. Declaring `earnings` as an abstract method in `Employee` enables the calls to `earnings` through `Employee` variables to compile and forces every direct concrete subclass of `Employee` to override `earnings`.

Method `toString` in class `Employee` returns a `String` containing the first name, last name and social security number of the employee. As we’ll see, each subclass of `Employee` overrides method `toString` to create a `String` representation of an object of that class that contains the employee’s type (e.g., “salaried employee:”) followed by the rest of the employee’s information.

The diagram in Fig. 10.3 shows each of the five classes in the hierarchy down the left side and methods `earnings` and `toString` across the top. For each class, the diagram shows the desired results of each method. We do not list superclass `Employee`’s `get` and `set` methods because they’re not overridden in any of the subclasses—each of these methods is inherited and used “as is” by each subclass.

Let’s consider class `Employee`’s declaration (Fig. 10.4). The class includes a constructor that takes the first name, last name and social security number as arguments (lines 11–16); `get` methods that return the first name, last name and social security number (lines 25–28, 37–40 and 49–52, respectively); `set` methods that set the first name, last name and social security number (lines 19–22, 31–34 and 43–46, respectively); method `toString` (lines 55–60), which returns the `String` representation of an `Employee`; and abstract method `earnings` (line 63), which will be implemented by each of the concrete subclasses. The `Employee` constructor does not validate its parameters in this example; normally, such validation should be provided.

|                                      | earnings                                                                                                                        | toString                                                                                                                                                                                                                |
|--------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Employee                             | abstract                                                                                                                        | <i>firstName lastName</i><br>social security number: <i>SSN</i>                                                                                                                                                         |
| Salaried-<br>Employee                | weeklySalary                                                                                                                    | salaried employee: <i>firstName lastName</i><br>social security number: <i>SSN</i><br>weekly salary: <i>weeklySalary</i>                                                                                                |
| Hourly-<br>Employee                  | <pre>if (hours &lt;= 40)     wage * hours else if (hours &gt; 40) {     40 * wage +     ( hours - 40 ) *     wage * 1.5 }</pre> | hourly employee: <i>firstName lastName</i><br>social security number: <i>SSN</i><br>hourly wage: <i>wage</i> ; hours worked: <i>hours</i>                                                                               |

43 public void setSocialSecurityNumber( String ssn )
44 {
45     socialSecurityNumber = ssn; // should validate
46 } // end method setSocialSecurityNumber
47
48 // return social security number
49 public String getSocialSecurityNumber()
50 {
51     return socialSecurityNumber;
52 } // end method getSocialSecurityNumber
53
54 // return String representation of Employee object
55 @Override
56 public String toString()
57 {
58     return String.format( "%s %s\nsocial security number: %s",
59         getFirstName(), getLastName(), getSocialSecurityNumber() );
60 } // end method toString
61
62 // abstract method overridden by concrete subclasses
63 public abstract double earnings(); // no implementation here
64 } // end abstract class Employee

```

**Fig. 10.4** | Employee abstract superclass. (Part 2 of 2.)

Why did we decide to declare `earnings` as an abstract method? It simply does not make sense to provide an implementation of this method in class `Employee`. We cannot calculate the earnings for a *general* `Employee`—we first must know the *specific* type of `Employee` to determine the appropriate earnings calculation. By declaring this method

abstract, we indicate that each concrete subclass *must* provide an appropriate earnings implementation and that a program will be able to use superclass `Employee` variables to invoke method `earnings` polymorphically for any type of `Employee`.

### 10.5.2 Concrete Subclass `SalariedEmployee`

Class `SalariedEmployee` (Fig. 10.5) extends class `Employee` (line 4) and overrides abstract method `earnings` (lines 33–37), which makes `SalariedEmployee` a concrete class. The class includes a constructor (lines 9–14) that takes a first name, a last name, a social security number and a weekly salary as arguments; a `set` method to assign a new nonnegative value to instance variable `weeklySalary` (lines 17–24); a `get` method to return `weeklySalary`'s value (lines 27–30); a method `earnings` (lines 33–37) to calculate a `SalariedEmployee`'s earnings; and a method `toString` (lines 40–45), which returns a `String` including the employee's type, namely, "salaried employee: " followed by employee-specific information produced by superclass `Employee`'s `toString` method and `SalariedEmployee`'s `getWeeklySalary` method. Class `SalariedEmployee`'s constructor passes the first name, last name and social security number to the `Employee` constructor (line 12) to initialize the private instance variables not inherited from the superclass. Method `earnings` overrides `Employee`'s abstract method `earnings` to provide a concrete implementation that returns the `SalariedEmployee`'s weekly salary. If we do not implement `earnings`, class `SalariedEmployee` must be declared abstract—otherwise, class `SalariedEmployee` will not compile. Of course, we want `SalariedEmployee` to be a concrete class in this example.

---

```

1 // Fig. 10.5: SalariedEmployee.java
2 // SalariedEmployee concrete class extends abstract class Employee.
3
4 public class SalariedEmployee extends Employee
5 {
6     private double weeklySalary;
7
8     // four-argument constructor
9     public SalariedEmployee( String first, String last, String ssn,
10        double salary )
11     {
12         super( first, last, ssn ); // pass to Employee constructor
13         setWeeklySalary( salary ); // validate and store salary
14     } // end four-argument SalariedEmployee constructor
15
16     // set salary
17     public void setWeeklySalary( double salary )
18     {
19         if ( salary >= 0.0 )
20             baseSalary = salary;
21         else
22             throw new IllegalArgumentException(
23                 "Weekly salary must be >= 0.0" );
24     } // end method setWeeklySalary
25

```

---

**Fig. 10.5** | `SalariedEmployee` concrete class extends abstract class `Employee`. (Part 1 of 2.)

```

26 // return salary
27 public double getWeeklySalary()
28 {
29     return weeklySalary;
30 } // end method getWeeklySalary
31
32 // calculate earnings; override abstract method earnings in Employee
33 @Override
34 public double earnings()
35 {
36     return getWeeklySalary();
37 } // end method earnings
38
39 // return String representation of SalariedEmployee object
40 @Override
41 public String toString()
42 {
43     return String.format( "salaried employee: %s\n%s: $%,.2f",
44         super.toString(), "weekly salary", getWeeklySalary() );
45 } // end method toString
46 } // end class SalariedEmployee

```

**Fig. 10.5** | SalariedEmployee concrete class extends abstract class Employee. (Part 2 of 2.)

Method `toString` (lines 40–45) overrides `Employee` method `toString`. If class `SalariedEmployee` did not override `toString`, `SalariedEmployee` would have inherited the `Employee` version of `toString`. In that case, `SalariedEmployee`'s `toString` method would simply return the employee's full name and social security number, which does not adequately represent a `SalariedEmployee`. To produce a complete `String` representation of a `SalariedEmployee`, the subclass's `toString` method returns "salaried employee: " followed by the superclass `Employee`-specific information (i.e., first name, last name and social security number) obtained by invoking the superclass's `toString` method (line 44)—this is a nice example of code reuse. The `String` representation of a `SalariedEmployee` also contains the employee's weekly salary obtained by invoking the class's `getWeeklySalary` method.

### 10.5.3 Concrete Subclass `HourlyEmployee`

Class `HourlyEmployee` (Fig. 10.6) also extends `Employee` (line 4). The class includes a constructor (lines 10–16) that takes as arguments a first name, a last name, a social security number, an hourly wage and the number of hours worked. Lines 19–26 and 35–42 declare *set* methods that assign new values to instance variables `wage` and `hours`, respectively. Method `setWage` (lines 19–26) ensures that `wage` is nonnegative, and method `setHours` (lines 35–42) ensures that `hours` is between 0 and 168 (the total number of hours in a week) inclusive. Class `HourlyEmployee` also includes *get* methods (lines 29–32 and 45–48) to return the values of `wage` and `hours`, respectively; a method `earnings` (lines 51–58) to calculate an `HourlyEmployee`'s earnings; and a method `toString` (lines 61–67), which returns a `String` containing the employee's type ("hourly employee: ") and the employee-specific information. The `HourlyEmployee` constructor, like the `SalariedEmployee` constructor, passes the first name, last name and social security number to the superclass `Employee` constructor

(line 13) to initialize the private instance variables. In addition, method `toString` calls superclass method `toString` (line 65) to obtain the `Employee`-specific information (i.e., first name, last name and social security number)—this is another nice example of code reuse.

---

```

1 // Fig. 10.6: HourlyEmployee.java
2 // HourlyEmployee class extends Employee.
3
4 public class HourlyEmployee extends Employee
5 {
6     private double wage; // wage per hour
7     private double hours; // hours worked for week
8
9     // five-argument constructor
10    public HourlyEmployee( String first, String last, String ssn,
11        double hourlyWage, double hoursWorked )
12    {
13        super( first, last, ssn );
14        setWage( hourlyWage ); // validate hourly wage
15        setHours( hoursWorked ); // validate hours worked
16    } // end five-argument HourlyEmployee constructor
17
18    // set wage
19    public void setWage( double hourlyWage )
20    {
21        if ( hourlyWage >= 0.0 )
22            wage = hourlyWage;
23        else
24            throw new IllegalArgumentException(
25                "Hourly wage must be >= 0.0" );
26    } // end method setWage
27
28    // return wage
29    public double getWage()
30    {
31        return wage;
32    } // end method getWage
33
34    // set hours worked
35    public void setHours( double hoursWorked )
36    {
37        if ( ( hoursWorked >= 0.0 ) && ( hoursWorked <= 168.0 ) )
38            hours = hoursWorked;
39        else
40            throw new IllegalArgumentException(
41                "Hours worked must be >= 0.0 and <= 168.0" );
42    } // end method setHours
43
44    // return hours worked
45    public double getHours()
46    {
47        return hours;
48    } // end method getHours

```

---

**Fig. 10.6** | HourlyEmployee class extends Employee. (Part I of 2.)

```

49
50 // calculate earnings; override abstract method earnings in Employee
51 @Override
52 public double earnings()
53 {
54     if ( getHours() <= 40 ) // no overtime
55         return getWage() * getHours();
56     else
57         return 40 * getWage() + ( getHours() - 40 ) * getWage() * 1.5;
58 } // end method earnings
59
60 // return String representation of HourlyEmployee object
61 @Override
62 public String toString()
63 {
64     return String.format( "hourly employee: %s\n%s: $%,.2f; %s: $%,.2f",
65         super.toString(), "hourly wage", getWage(),
66         "hours worked", getHours() );
67 } // end method toString
68 } // end class HourlyEmployee

```

**Fig. 10.6** | HourlyEmployee class extends Employee. (Part 2 of 2.)

### 10.5.4 Concrete Subclass CommissionEmployee

Class `CommissionEmployee` (Fig. 10.7) extends class `Employee` (line 4). The class includes a constructor (lines 10–16) that takes a first name, a last name, a social security number, a sales amount and a commission rate; *set* methods (lines 19–26 and 35–42) to assign new values to instance variables `commissionRate` and `grossSales`, respectively; *get* methods (lines 29–32 and 45–48) that retrieve the values of these instance variables; method `earnings` (lines 51–55) to calculate a `CommissionEmployee`'s earnings; and method `toString` (lines 58–65), which returns the employee's type, namely, "commission employee: " and employee-specific information. The constructor also passes the first name, last name and social security number to `Employee`'s constructor (line 13) to initialize `Employee`'s private instance variables. Method `toString` calls superclass method `toString` (line 62) to obtain the `Employee`-specific information (i.e., first name, last name and social security number).

```

1 // Fig. 10.7: CommissionEmployee.java
2 // CommissionEmployee class extends Employee.

4 public class CommissionEmployee extends Employee
5 {
6     private double grossSales; // gross weekly sales
7     private double commissionRate; // commission percentage
8
9     // five-argument constructor
10    public CommissionEmployee( String first, String last, String ssn,
11        double sales, double rate )
12    {
13        super( first, last, ssn );

```

**Fig. 10.7** | CommissionEmployee class extends Employee. (Part 1 of 2.)

```

14     setGrossSales( sales );
15     setCommissionRate( rate );
16 } // end five-argument CommissionEmployee constructor
17
18 // set commission rate
19 public void setCommissionRate( double rate )
20 {
21     if ( rate > 0.0 && rate < 1.0 )
22         commissionRate = rate;
23     else
24         throw new IllegalArgumentException(
25             "Commission rate must be > 0.0 and < 1.0" );
26 } // end method setCommissionRate
27
28 // return commission rate
29 public double getCommissionRate()
30 {
31     return commissionRate;
32 } // end method getCommissionRate
33
34 // set gross sales amount
35 public void setGrossSales( double sales )
36 {
37     if ( sales >= 0.0 )
38         grossSales = sales;
39     else
40         throw new IllegalArgumentException(
41             "Gross sales must be >= 0.0" );
42 } // end method setGrossSales
43
44 // return gross sales amount
45 public double getGrossSales()
46 {
47     return grossSales;
48 } // end method getGrossSales
49
50 // calculate earnings; override abstract method earnings in Employee
51 @Override
52 public double earnings()
53 {
54     return getCommissionRate() * getGrossSales();
55 } // end method earnings
56
57 // return String representation of CommissionEmployee object
58 @Override
59 public String toString()
60 {
61     return String.format( "%s: %s\n%s: $%,.2f; %s: %.2f",
62         "commission employee", super.toString(),
63         "gross sales", getGrossSales(),
64         "commission rate", getCommissionRate() );
65 } // end method toString
66 } // end class CommissionEmployee

```

**Fig. 10.7** | CommissionEmployee class extends Employee. (Part 2 of 2.)

### 10.5.5 Indirect Concrete Subclass BasePlusCommissionEmployee

Class `BasePlusCommissionEmployee` (Fig. 10.8) extends class `CommissionEmployee` (line 4) and therefore is an *indirect* subclass of class `Employee`. Class `BasePlusCommissionEmployee` has a constructor (lines 9–14) that takes as arguments a first name, a last name, a social security number, a sales amount, a commission rate and a base salary. It then passes all of these except the base salary to the `CommissionEmployee` constructor (line 12) to initialize the inherited members. `BasePlusCommissionEmployee` also contains a *set* method (lines 17–24) to assign a new value to instance variable `baseSalary` and a *get* method (lines 27–30) to return `baseSalary`'s value. Method `earnings` (lines 33–37) calculates a `BasePlusCommissionEmployee`'s earnings. Line 36 in method `earnings` calls superclass `CommissionEmployee`'s `earnings` method to calculate the commission-based portion of the employee's earnings—this is another nice example of code reuse. `BasePlusCommissionEmployee`'s `toString` method (lines 40–46) creates a `String` representation of a `BasePlusCommissionEmployee` that contains "base-salaried", followed by the `String` obtained by invoking superclass `CommissionEmployee`'s `toString` method (another example of code reuse), then the base salary. The result is a `String` beginning with "base-salaried commission employee" followed by the rest of the `BasePlusCommissionEmployee`'s information. Recall that `CommissionEmployee`'s `toString` obtains the employee's first name, last name and social security number by invoking the `toString` method of its superclass (i.e., `Employee`)—yet another example of code reuse. `BasePlusCommissionEmployee`'s `toString` initiates a chain of method calls that span all three levels of the `Employee` hierarchy.

### 10.5.6 Polymorphic Processing, Operator instanceof and Downcasting

To test our Employee hierarchy, the application in Fig. 10.9 creates an object of each of the four concrete classes SalariedEmployee, HourlyEmployee, CommissionEmployee and BasePlusCommissionEmployee. The program manipulates these objects nonpolymorphically, via variables of each object's own type, then polymorphically, using an array of Employee variables. While processing the objects polymorphically, the program increases the base salary of each BasePlusCommissionEmployee by 10%—this requires *determining the object's type at execution time*. Finally, the program polymorphically determines and outputs the type of each object in the Employee array. Lines 9–18 create objects of each of the four concrete Employee subclasses. Lines 22–30 output the String representation and earnings of each of these objects *nonpolymorphically*. Each object's toString method is called *implicitly* by printf when the object is output as a String with the %s format specifier.

```

```

11 HourlyEmployee hourlyEmployee =
12     new HourlyEmployee( "Karen", "Price", "222-22-2222", 16.75, 40 );
13 CommissionEmployee commissionEmployee =
14     new CommissionEmployee(
15         "Sue", "Jones", "333-33-3333", 10000, .06 );
16 BasePlusCommissionEmployee basePlusCommissionEmployee =
17     new BasePlusCommissionEmployee(
18         "Bob", "Lewis", "444-44-4444", 5000, .04, 300 );
19
20 System.out.println( "Employees processed individually:\n" );
21
22 System.out.printf( "%s\n%s: $%,.2f\n\n",
23     salariedEmployee, "earned", salariedEmployee.earnings() );
24 System.out.printf( "%s\n%s: $%,.2f\n\n",
25     hourlyEmployee, "earned", hourlyEmployee.earnings() );
26 System.out.printf( "%s\n%s: $%,.2f\n\n",
27     commissionEmployee, "earned", commissionEmployee.earnings() );
28 System.out.printf( "%s\n%s: $%,.2f\n\n",
29     basePlusCommissionEmployee,
30     "earned", basePlusCommissionEmployee.earnings() );
31
32 // create four-element Employee array
33 Employee[] employees = new Employee[ 4 ];
34
35 // initialize array with Employees
36 employees[ 0 ] = salariedEmployee;
37 employees[ 1 ] = hourlyEmployee;
38 employees[ 2 ] = commissionEmployee;
39 employees[ 3 ] = basePlusCommissionEmployee;
40
41 System.out.println( "Employees processed polymorphically:\n" );
42
43 // generically process each element in array employees
44 for ( Employee currentEmployee : employees )
45 {
46     System.out.println( currentEmployee ); // invokes toString
47
48     // determine whether element is a BasePlusCommissionEmployee
49     if ( currentEmployee instanceof BasePlusCommissionEmployee )
50     {
51         // downcast Employee reference to
52         // BasePlusCommissionEmployee reference
53         BasePlusCommissionEmployee employee =
54             ( BasePlusCommissionEmployee ) currentEmployee;
55
56         employee.setBaseSalary( 1.10 * employee.getBaseSalary() );
57
58         System.out.printf(
59             "new base salary with 10%% increase is: $%,.2f\n",
60             employee.getBaseSalary() );
61     } // end if
62

```

**Fig. 10.9** | Employee hierarchy test program. (Part 2 of 4.)

```

63         System.out.printf(
64             "earned $%,.2F\n\n", currentEmployee.earnings() );
65     } // end for
66
67     // get type name of each object in employees array
68     for ( int j = 0; j < employees.length; j++ )
69         System.out.printf( "Employee %d is a %s\n", j,
70             employees[ j ].getClass().getName() );
71     } // end main
72 } // end class PayrollSystemTest

```

Employees processed individually:

salaried employee: John Smith  
social security number: 111-11-1111  
weekly salary: \$800.00  
earned: \$800.00

hourly employee: Karen Price  
social security number: 222-22-2222  
hourly wage: \$16.75; hours worked: 40.00  
earned: \$670.00

commission employee: Sue Jones  
social security number: 333-33-3333  
gross sales: \$10,000.00; commission rate: 0.06  
earned: \$600.00

base-salaried commission employee: Bob Lewis  
social security number: 444-44-4444  
gross sales: \$5,000.00; commission rate: 0.04; base salary: \$300.00  
earned: \$500.00

Employees processed polymorphically:

salaried employee: John Smith  
social security number: 111-11-1111  
weekly salary: \$800.00  
earned \$800.00

hourly employee: Karen Price  
social security number: 222-22-2222  
hourly wage: \$16.75; hours worked: 40.00  
earned \$670.00

commission employee: Sue Jones  
social security number: 333-33-3333  
gross sales: \$10,000.00; commission rate: 0.06  
earned \$600.00

base-salaried commission employee: Bob Lewis  
social security number: 444-44-4444  
gross sales: \$5,000.00; commission rate: 0.04; base salary: \$300.00  
new base salary with 10% increase is: \$330.00  
earned \$530.00

```

**Fig. 10.9** | Employee hierarchy test program. (Part 4 of 4.)

### *Creating the Array of Employees*

Line 33 declares `employees` and assigns it an array of four `Employee` variables. Line 36 assigns the reference to a `SalariedEmployee` object to `employees[0]`. Line 37 assigns the reference to an `HourlyEmployee` object to `employees[1]`. Line 38 assigns the reference to a `CommissionEmployee` object to `employees[2]`. Line 39 assigns the reference to a `BasePlusCommissionEmployee` object to `employees[3]`. These assignments are allowed, because a `SalariedEmployee` *is an* `Employee`, an `HourlyEmployee` *is an* `Employee`, a `CommissionEmployee` *is an* `Employee` and a `BasePlusCommissionEmployee` *is an* `Employee`. Therefore, we can assign the references of `SalariedEmployee`, `HourlyEmployee`, `CommissionEmployee` and `BasePlusCommissionEmployee` objects to superclass `Employee` variables, *even though* `Employee` *is an abstract class*.

### *Polymorphically Processing Employees*

Lines 44–65 iterate through array `employees` and invoke methods `toString` and `earnings` with `Employee` variable `currentEmployee`, which is assigned the reference to a different `Employee` in the array on each iteration. The output illustrates that the appropriate methods for each class are indeed invoked. All calls to method `toString` and `earnings` are resolved at execution time, based on the type of the object to which `currentEmployee` refers. This process is known as **dynamic binding** or **late binding**. For example, line 46 *implicitly* invokes method `toString` of the object to which `currentEmployee` refers. As a result of dynamic binding, Java decides which class's `toString` method to call *at execution time rather than at compile time*. Only the methods of class `Employee` can be called via an `Employee` variable (and `Employee`, of course, includes the methods of class `Object`). A superclass reference can be used to invoke only methods of the superclass—the subclass method implementations are invoked polymorphically.

### *Performing Type-Specific Operations on BasePlusCommissionEmployees*

We perform special processing on `BasePlusCommissionEmployee` objects—as we encounter these objects at execution time, we increase their base salary by 10%. When processing objects polymorphically, we typically do not need to worry about the “specifics,” but to adjust the base salary, we *do* have to determine the specific type of `Employee` object at execution time. Line 49 uses the **instanceof** operator to determine whether a particular `Employee` object's type is `BasePlusCommissionEmployee`. The condition in line 49 is true if the object referenced by `currentEmployee` *is a* `BasePlusCommissionEmployee`. This would also be true for any object of a `BasePlusCommissionEmployee` subclass because of the *is-a* relationship a subclass has with its superclass. Lines 53–54 downcast `currentEmployee` from type `Employee` to type `BasePlusCommissionEmployee`—this cast is allowed only if the object has an *is-a* relationship with `BasePlusCommissionEmployee`. The condition at line 49 ensures that this is the case. This cast is required if we're to invoke subclass `BasePlusCommissionEmployee` methods `getBaseSalary` and `setBaseSalary` on the cur-

rent `Employee` object—as you’ll see momentarily, *attempting to invoke a subclass-only method directly on a superclass reference is a compilation error.*

### Common Programming Error 10.3

*Assigning a superclass variable to a subclass variable (without an explicit cast) is a compilation error.*

### Software Engineering Observation 10.4

*If a subclass object’s reference has been assigned to a variable of one of its direct or indirect superclasses at execution time, it’s acceptable to downcast the reference stored in that superclass variable back to a subclass-type reference. Before performing such a cast, use the `instanceof` operator to ensure that the object is indeed an object of an appropriate subclass.*

### Common Programming Error 10.4

*When downcasting a reference, a `ClassCastException` occurs if the referenced object at execution time does not have an is-a relationship with the type specified in the cast operator.*

If the `instanceof` expression in line 49 is true, lines 53–60 perform the special processing required for the `BasePlusCommissionEmployee` object. Using `BasePlusCommissionEmployee` variable `employee`, line 56 invokes subclass-only methods `getBaseSalary` and `setBaseSalary` to retrieve and update the employee’s base salary with the 10% raise.

### Calling earnings Polymorphically

Lines 63–64 invoke method `earnings` on `currentEmployee`, which polymorphically calls the appropriate subclass object’s `earnings` method. Obtaining the earnings of the `SalariedEmployee`, `HourlyEmployee` and `CommissionEmployee` polymorphically in lines 63–64 produces the same results as obtaining these employees’ earnings individually in lines 22–27. The earnings amount obtained for the `BasePlusCommissionEmployee` in lines 63–64 is higher than that obtained in lines 28–30, due to the 10% increase in its base salary.

### Using Reflection to Get Each Employee’s Class Name

Lines 68–70 display each employee’s type as a `String`, using basic features of Java’s so-called reflection capabilities. Every object knows its own class and can access this information through the `getClass` method, which all classes inherit from class `Object`. Method `getClass` returns an object of type `Class` (from package `java.lang`), which contains information about the object’s type, including its class name. Line 70 invokes `getClass` on the current object to get its runtime class. The result of the `getClass` call is used to invoke `getName` to get the object’s class name.

### Avoiding Compilation Errors with Downcasting

In the previous example, we avoided several compilation errors by downcasting an `Employee` variable to a `BasePlusCommissionEmployee` variable in lines 53–54. If you remove the cast operator (`BasePlusCommissionEmployee`) from line 54 and attempt to assign `Employee` variable `currentEmployee` directly to `BasePlusCommissionEmployee` variable `employee`, you’ll receive an “incompatible types” compilation error. This error indicates that the attempt to assign the reference of superclass object `currentEmployee` to subclass variable `employee` is not allowed. The compiler prevents this assignment because a `CommissionEmployee` is not a `BasePlusCommissionEmployee`—*the is-a relationship applies only between the subclass and its superclasses, not vice versa.*

Similarly, if lines 56 and 60 used superclass variable `currentEmployee` to invoke subclass-only methods `getBaseSalary` and `setBaseSalary`, we'd receive "cannot find symbol" compilation errors at these lines. Attempting to invoke subclass-only methods via a superclass variable is not allowed—even though lines 56 and 60 execute only if `instanceof` in line 49 returns true to indicate that `currentEmployee` holds a reference to a `BasePlusCommissionEmployee` object. Using a superclass `Employee` variable, we can invoke only methods found in class `Employee`—`earnings`, `toString` and `Employee`'s `get` and `set` methods.

### Software Engineering Observation 10.5

*Although the actual method that's called depends on the runtime type of the object to which a variable refers, a variable can be used to invoke only those methods that are members of that variable's type, which the compiler verifies.*

## 10.5.7 Summary of the Allowed Assignments Between Superclass and Subclass Variables

Now that you've seen a complete application that processes diverse subclass objects polymorphically, we summarize what you can and cannot do with superclass and subclass objects and variables. Although a subclass object also *is a* superclass object, the two objects are nevertheless different. As discussed previously, subclass objects can be treated as objects of their superclass. But because the subclass can have additional subclass-only members, assigning a superclass reference to a subclass variable is not allowed without an explicit cast—such an assignment would leave the subclass members undefined for the superclass object.

We've discussed four ways to assign superclass and subclass references to variables of superclass and subclass types:

1. Assigning a superclass reference to a superclass variable is straightforward.
2. Assigning a subclass reference to a subclass variable is straightforward.
3. Assigning a subclass reference to a superclass variable is safe, because the subclass object *is an* object of its superclass. However, the superclass variable can be used to refer *only* to superclass members. If this code refers to subclass-only members through the superclass variable, the compiler reports errors.
4. Attempting to assign a superclass reference to a subclass variable is a compilation error. To avoid this error, the superclass reference must be cast to a subclass type explicitly. At *execution time*, if the object to which the reference refers *is not* a subclass object, an exception will occur. (For more on exception handling, see Chapter 11.) You should use the `instanceof` operator to ensure that such a cast is performed only if the object is a subclass object.

## 10.6 final Methods and Classes

We saw in Sections 6.3 and 6.10 that variables can be declared `final` to indicate that they cannot be modified after they're initialized—such variables represent constant values. It's also possible to declare methods, method parameters and classes with the `final` modifier.

### *Final Methods Cannot Be Overridden*

A **final method** in a superclass *cannot* be overridden in a subclass—this guarantees that the `final` method implementation will be used by all direct and indirect subclasses in the

hierarchy. Methods that are declared `private` are implicitly `final`, because it's not possible to override them in a subclass. Methods that are declared `static` are also implicitly `final`. A `final` method's declaration can never change, so all subclasses use the same method implementation, and calls to `final` methods are resolved at compile time—this is known as **static binding**.

### *Final Classes Cannot Be Superclasses*

A **final class** that's declared `final` cannot be a superclass (i.e., a class cannot extend a `final` class). All methods in a `final` class are implicitly `final`. Class `String` is an example of a `final` class. If you were allowed to create a subclass of `String`, objects of that subclass could be used wherever `Strings` are expected. Since class `String` cannot be extended, programs that use `Strings` can rely on the functionality of `String` objects as specified in the Java API. Making the class `final` also prevents programmers from creating subclasses that might bypass security restrictions. For more insights on the use of keyword `final`, visit

[download.oracle.com/javase/tutorial/java/IandI/final.html](http://download.oracle.com/javase/tutorial/java/IandI/final.html)

and

[www.ibm.com/developerworks/java/library/j-jtp1029.html](http://www.ibm.com/developerworks/java/library/j-jtp1029.html)

### Common Programming Error 10.5

*Attempting to declare a subclass of a `final` class is a compilation error.*

### Software Engineering Observation 10.6

*In the Java API, the vast majority of classes are not declared `final`. This enables inheritance and polymorphism. However, in some cases, it's important to declare classes `final`—typically for security reasons.*

## 10.7 Case Study: Creating and Using Interfaces

Our next example (Figs. 10.11–10.15) reexamines the payroll system of Section 10.5. Suppose that the company involved wishes to perform several accounting operations in a single accounts payable application—in addition to calculating the earnings that must be paid to each employee, the company must also calculate the payment due on each of several invoices (i.e., bills for goods purchased). Though applied to unrelated things (i.e., employees and invoices), both operations have to do with obtaining some kind of payment amount. For an employee, the payment refers to the employee's earnings. For an invoice, the payment refers to the total cost of the goods listed on the invoice. Can we calculate such *different* things as the payments due for employees and invoices in *a single* application polymorphically? Does Java offer a capability requiring that *unrelated* classes implement a set of *common* methods (e.g., a method that calculates a payment amount)? Java **interfaces** offer exactly this capability.

### *Standardizing Interactions*

Interfaces define and standardize the ways in which things such as people and systems can interact with one another. For example, the controls on a radio serve as an interface between radio users and a radio's internal components. The controls allow users to perform

only a limited set of operations (e.g., change the station, adjust the volume, choose between AM and FM), and different radios may implement the controls in different ways (e.g., using push buttons, dials, voice commands). The interface specifies *what* operations a radio must permit users to perform but does not specify *how* the operations are performed.

### Software Objects Communicate Via Interfaces

Software objects also communicate via interfaces. A Java interface describes a set of methods that can be called on an object to tell it, for example, to perform some task or return some piece of information. The next example introduces an interface named `Payable` to describe the functionality of any object that must be capable of being paid and thus must offer a method to determine the proper payment amount due. An **interface declaration** begins with the keyword **interface** and contains only constants and abstract methods. Unlike classes, all interface members must be `public`, and *interfaces may not specify any implementation details*, such as concrete method declarations and instance variables. All methods declared in an interface are implicitly `public` abstract methods, and all fields are implicitly `public`, `static` and `final`. [Note: As of Java SE 5, it became a better programming practice to declare sets of constants as enumerations with keyword `enum`. See Section 6.10 for an introduction to `enum` and Section 8.9 for additional `enum` details.]

#### Good Programming Practice 10.1

According to Chapter 9 of the Java Language Specification, it's proper style to declare an interface's methods without keywords `public` and `abstract`, because they're redundant in interface method declarations. Similarly, constants should be declared without keywords `public`, `static` and `final`, because they, too, are redundant.

### Using an Interface

To use an interface, a concrete class must specify that it **implements** the interface and must declare each method in the interface with the signature specified in the interface declaration. To specify that a class implements an interface add the `implements` keyword and the name of the interface to the end of your class declaration's first line. A class that does not implement *all* the methods of the interface is an *abstract* class and must be declared `abstract`. Implementing an interface is like signing a *contract* with the compiler that states, "I will declare all the methods specified by the interface or I will declare my class `abstract`."

#### Common Programming Error 10.6

Failing to implement any method of an interface in a concrete class that implements the interface results in a compilation error indicating that the class must be declared `abstract`.

### Relating Disparate Types

An interface is often used when disparate (i.e., unrelated) classes need to share common methods and constants. This allows objects of unrelated classes to be processed polymorphically—objects of classes that implement the same interface can respond to the same method calls. You can create an interface that describes the desired functionality, then implement this interface in any classes that require that functionality. For example, in the accounts payable application developed in this section, we implement interface `Payable` in any class that must be able to calculate a payment amount (e.g., `Employee`, `Invoice`).

### Interfaces vs. Abstract Classes

An interface is often used in place of an abstract class when there's no default implementation to inherit—that is, no fields and no default method implementations. Like public abstract classes, interfaces are typically public types. Like a public class, a public interface must be declared in a file with the same name as the interface and the .java file-name extension.

### Tagging Interfaces

We'll see in Chapter 17, Files, Streams and Object Serialization, the notion of “tagging interfaces”—empty interfaces that have *no* methods or constant values. They're used to add *is-a* relationships to classes. For example, in Chapter 17 we'll discuss a mechanism called object serialization, which can convert objects to byte representations and can convert those byte representations back to objects. To enable this mechanism to work with your objects, you simply have to mark them as `Serializable` by adding `implements Serializable` to the end of your class declaration's first line. Then, all the objects of your class have the *is-a* relationship with `Serializable`.

## 10.7.1 Developing a Payable Hierarchy

To build an application that can determine payments for employees and invoices alike, we first create interface `Payable`, which contains method `getPaymentAmount` that returns a `double` amount that must be paid for an object of any class that implements the interface. Method `getPaymentAmount` is a general-purpose version of method `earnings` of the `Employee` hierarchy—method `earnings` calculates a payment amount specifically for an `Employee`, while `getPaymentAmount` can be applied to a broad range of unrelated objects. After declaring interface `Payable`, we introduce class `Invoice`, which implements interface `Payable`. We then modify class `Employee` such that it also implements interface `Payable`. Finally, we update `Employee` subclass `SalariedEmployee` to “fit” into the `Payable` hierarchy by renaming `SalariedEmployee` method `earnings` as `getPaymentAmount`.

### Good Programming Practice 10.2

*When declaring a method in an interface, choose a method name that describes the method's purpose in a general manner, because the method may be implemented by many unrelated classes.*

Classes `Invoice` and `Employee` both represent things for which the company must be able to calculate a payment amount. Both classes implement the `Payable` interface, so a program can invoke method `getPaymentAmount` on `Invoice` objects and `Employee` objects alike. As we'll soon see, this enables the polymorphic processing of `Invoices` and `Employees` required for the company's accounts payable application.

The UML class diagram in Fig. 10.10 shows the hierarchy used in our accounts payable application. The hierarchy begins with interface `Payable`. The UML distinguishes an interface from other classes by placing the word “interface” in guillemets (« and ») above the interface name. The UML expresses the relationship between a class and an interface through a relationship known as **realization**. A class is said to “realize,” or implement, the methods of an interface. A class diagram models a realization as a dashed arrow with a hollow arrowhead pointing from the implementing class to the interface. The diagram in Fig. 10.10 indicates that classes `Invoice` and `Employee` each realize (i.e., implement) inter-

face `Payable`. As in the class diagram of Fig. 10.2, class `Employee` appears in italics, indicating that it's an abstract class. Concrete class `SalariedEmployee` extends `Employee` and inherits its superclass's realization relationship with interface `Payable`.

**Fig. 10.10** | `Payable` interface hierarchy UML class diagram.

### 10.7.2 Interface `Payable`

The declaration of interface `Payable` begins in Fig. 10.11 at line 4. Interface `Payable` contains public abstract method `getPaymentAmount` (line 6). The method is not explicitly declared `public` or `abstract`. Interface methods are always `public` and `abstract`, so they do not need to be declared as such. Interface `Payable` has only one method—interfaces can have any number of methods. In addition, method `getPaymentAmount` has no parameters, but interface methods *can* have parameters. Interfaces may also contain fields that are implicitly `final` and `static`.

```

1 // Fig. 10.11: Payable.java
2 // Payable interface declaration.
3
4 public interface Payable
5 {
6     double getPaymentAmount(); // calculate payment; no implementation
7 } // end interface Payable
  
```

**Fig. 10.11** | `Payable` interface declaration.

### 10.7.3 Class `Invoice`

We now create class `Invoice` (Fig. 10.12) to represent a simple invoice that contains billing information for only one kind of part. The class declares private instance variables `partNumber`, `partDescription`, `quantity` and `pricePerItem` (in lines 6–9) that indicate the part number, a description of the part, the quantity of the part ordered and the price per item. Class `Invoice` also contains a constructor (lines 12–19), *get* and *set* methods (lines 22–74) that manipulate the class's instance variables and a `toString` method (lines 77–83) that returns a `String` representation of an `Invoice` object. Methods `setQuantity` (lines 46–52) and `setPricePerItem` (lines 61–68) ensure that `quantity` and `pricePerItem` obtain only nonnegative values.

```
1 // Fig. 10.12: Invoice.java
2 // Invoice class that implements Payable.
3
4 public class Invoice implements Payable
5 {
6     private String partNumber;
7     private String partDescription;
8     private int quantity;
9     private double pricePerItem;
10
11     // four-argument constructor
12     public Invoice( String part, String description, int count,
13         double price )
14     {
15         partNumber = part;
16         partDescription = description;
17         setQuantity( count ); // validate and store quantity
18         setPricePerItem( price ); // validate and store price per item
19     } // end four-argument Invoice constructor
20
21     // set part number
22     public void setPartNumber( String part )
23     {
24         partNumber = part; // should validate
25     } // end method setPartNumber
26
27     // get part number
28     public String getPartNumber()
29     {
30         return partNumber;
31     } // end method getPartNumber
32
33     // set description
34     public void setPartDescription( String description )
35     {
36         partDescription = description; // should validate
37     } // end method setPartDescription
38
39     // get description
40     public String getPartDescription()
41     {
42         return partDescription;
43     } // end method getPartDescription
44
45     // set quantity
46     public void setQuantity( int count )
47     {
48         if ( count >= 0 )
49             quantity = count;
50         else
51             throw new IllegalArgumentException( "Quantity must be >= 0" );
52     } // end method setQuantity
53
```

**Fig. 10.12** | Invoice class that implements Payable. (Part I of 2.)

```

54 // get quantity
55 public int getQuantity()
56 {
57     return quantity;
58 } // end method getQuantity
59
60 // set price per item
61 public void setPricePerItem( double price )
62 {
63     if ( price >= 0.0 )
64         pricePerItem = price;
65     else
66         throw new IllegalArgumentException(
67             "Price per item must be >= 0" );
68 } // end method setPricePerItem
69
70 // get price per item
71 public double getPricePerItem()
72 {
73     return pricePerItem;
74 } // end method getPricePerItem
75
76 // return String representation of Invoice object
77 @Override
78 public String toString()
79 {
80     return String.format( "%s: \n%s: %s (%s) \n%s: %d \n%s: $%,.2f",
81         "invoice", "part number", getPartNumber(), getPartDescription(),
82         "quantity", getQuantity(), "price per item", getPricePerItem() );
83 } // end method toString
84
85 // method required to carry out contract with interface Payable
86 @Override
87 public double getPaymentAmount()
88 {
89     return getQuantity() * getPricePerItem(); // calculate total cost
90 } // end method getPaymentAmount
91 } // end class Invoice

```

**Fig. 10.12** | Invoice class that implements Payable. (Part 2 of 2.)

Line 4 indicates that class `Invoice` implements interface `Payable`. Like all classes, class `Invoice` also implicitly extends `Object`. Java does not allow subclasses to inherit from more than one superclass, but it allows a class to inherit from one superclass and implement as many interfaces as it needs. To implement more than one interface, use a comma-separated list of interface names after keyword `implements` in the class declaration, as in:

```
public class ClassName extends SuperclassName implements FirstInterface,
    SecondInterface, ...
```

### Software Engineering Observation 10.7

All objects of a class that implement multiple interfaces have the is-a relationship with each implemented interface type.

Class `Invoice` implements the one method in interface `Payable`—method `getPaymentAmount` is declared in lines 86–90. The method calculates the total payment required to pay the invoice. The method multiplies the values of `quantity` and `pricePerItem` (obtained through the appropriate *get* methods) and returns the result (line 89). This method satisfies the implementation requirement for this method in interface `Payable`—we’ve fulfilled the interface contract with the compiler.

### 10.7.4 Modifying Class `Employee` to Implement Interface `Payable`

We now modify class `Employee` such that it implements interface `Payable`. Figure 10.13 contains the modified class, which is identical to that of Fig. 10.4 with two exceptions. First, line 4 of Fig. 10.13 indicates that class `Employee` now implements interface `Payable`. So we must rename `earnings` to `getPaymentAmount` throughout the `Employee` hierarchy. As with method `earnings` in the version of class `Employee` in Fig. 10.4, however, it does not make sense to implement method `getPaymentAmount` in class `Employee` because we cannot calculate the earnings payment owed to a general `Employee`—we must first know the specific type of `Employee`. In Fig. 10.4, we declared method `earnings` as abstract for this reason, so class `Employee` had to be declared abstract. This forced each `Employee` concrete subclass to override `earnings` with an implementation.

---

```

1 // Fig. 10.13: Employee.java
2 // Employee abstract superclass that implements Payable.
3
4 public abstract class Employee implements Payable
5 {
6     private String firstName;
7     private String lastName;
8     private String socialSecurityNumber;
9
10    // three-argument constructor
11    public Employee( String first, String last, String ssn )
12    {
13        firstName = first;
14        lastName = last;
15        socialSecurityNumber = ssn;
16    } // end three-argument Employee constructor
17
18    // set first name
19    public void setFirstName( String first )
20    {
21        firstName = first; // should validate
22    } // end method setFirstName
23
24    // return first name
25    public String getFirstName()
26    {
27        return firstName;
28    } // end method getFirstName
29

```

**Fig. 10.13** | `Employee` class that implements `Payable`. (Part I of 2.)

```

30 // set last name
31 public void setLastName( String last )
32 {
33     lastName = last; // should validate
34 } // end method setLastName
35
36 // return last name
37 public String getLastName()
38 {
39     return lastName;
40 } // end method getLastName
41
42 // set social security number
43 public void setSocialSecurityNumber( String ssn )
44 {
45     socialSecurityNumber = ssn; // should validate
46 } // end method setSocialSecurityNumber
47
48 // return social security number
49 public String getSocialSecurityNumber()
50 {
51     return socialSecurityNumber;
52 } // end method getSocialSecurityNumber
53
54 // return String representation of Employee object
55 @Override
56 public String toString()
57 {
58     return String.format( "%s %s\nsocial security number: %s",
59         getFirstName(), getLastName(), getSocialSecurityNumber() );
60 } // end method toString
61
62 // Note: We do not implement Payable method getPaymentAmount here so
63 // this class must be declared abstract to avoid a compilation error.
64 } // end abstract class Employee

```

**Fig. 10.13** | Employee class that implements Payable. (Part 2 of 2.)

In Fig. 10.13, we handle this situation differently. Recall that when a class implements an interface, it makes a *contract* with the compiler stating either that the class will implement *each* of the methods in the interface or that the class will be declared abstract. If the latter option is chosen, we do not need to declare the interface methods as abstract in the abstract class—they’re already implicitly declared as such in the interface. Any concrete subclass of the abstract class must implement the interface methods to fulfill the superclass’s contract with the compiler. If the subclass does not do so, it too must be declared abstract. As indicated by the comments in lines 62–63, class `Employee` of Fig. 10.13 does *not* implement method `getPaymentAmount`, so the class is declared abstract. Each direct `Employee` subclass *inherits the superclass’s contract* to implement method `getPaymentAmount` and thus must implement this method to become a concrete class for which objects can be instantiated. A class that extends one of `Employee`’s concrete subclasses will inherit an implementation of `getPaymentAmount` and thus will also be a concrete class.

### 10.7.5 Modifying Class `SalariedEmployee` for Use in the `Payable` Hierarchy

Figure 10.14 contains a modified `SalariedEmployee` class that extends `Employee` and fulfills superclass `Employee`'s contract to implement `Payable` method `getPaymentAmount`. This version of `SalariedEmployee` is identical to that of Fig. 10.5, but it replaces method `earnings` with method `getPaymentAmount` (lines 34–38). Recall that the `Payable` version of the method has a more *general* name to be applicable to possibly *disparate* classes. The remaining `Employee` subclasses (e.g., `HourlyEmployee`, `CommissionEmployee` and `BasePlusCommissionEmployee`) also must be modified to contain method `getPaymentAmount` in place of `earnings` to reflect the fact that `Employee` now implements `Payable`. We leave these modifications as an exercise (Exercise 10.11) and use only `SalariedEmployee` in our test program here. Exercise 10.12 asks you to implement interface `Payable` in the entire `Employee` class hierarchy of Figs. 10.4–10.9 without modifying the `Employee` subclasses.

When a class implements an interface, the same *is-a* relationship provided by inheritance applies. Class `Employee` implements `Payable`, so we can say that an `Employee` *is a* `Payable`. In fact, objects of any classes that extend `Employee` are also `Payable` objects. `SalariedEmployee` objects, for instance, are `Payable` objects. Objects of any subclasses of the class that implements the interface can also be thought of as objects of the interface type. Thus, just as we can assign the reference of a `SalariedEmployee` object to a superclass `Employee` variable, we can assign the reference of a `SalariedEmployee` object to an interface `Payable` variable. `Invoice` implements `Payable`, so an `Invoice` object also *is a* `Payable` object, and we can assign the reference of an `Invoice` object to a `Payable` variable.

#### Software Engineering Observation 10.8

*When a method parameter is declared with a superclass or interface type, the method processes the object received as an argument polymorphically.*

#### Software Engineering Observation 10.9

*Using a superclass reference, we can polymorphically invoke any method declared in the superclass and its superclasses (e.g., class `Object`). Using an interface reference, we can polymorphically invoke any method declared in the interface, its superinterfaces (one interface can extend another) and in class `Object`—a variable of an interface type must refer to an object to call methods, and all objects have the methods of class `Object`.*

```

1 // Fig. 10.14: SalariedEmployee.java
2 // SalariedEmployee class extends Employee, which implements Payable.
3
4 public class SalariedEmployee extends Employee
5 {
6     private double weeklySalary;
7
8     // four-argument constructor
9     public SalariedEmployee( String first, String last, String ssn,
10        double salary )
11     {

```

**Fig. 10.14** | `SalariedEmployee` class that implements interface `Payable` method `getPaymentAmount`. (Part 1 of 2.)

```

12     super( first, last, ssn ); // pass to Employee constructor
13     setWeeklySalary( salary ); // validate and store salary
14 } // end four-argument SalariedEmployee constructor
15
16 // set salary
17 public void setWeeklySalary( double salary )
18 {
19     if ( salary >= 0.0 )
20         baseSalary = salary;
21     else
22         throw new IllegalArgumentException(
23             "Weekly salary must be >= 0.0" );
24 } // end method setWeeklySalary
25
26 // return salary
27 public double getWeeklySalary()
28 {
29     return weeklySalary;
30 } // end method getWeeklySalary
31
32 // calculate earnings; implement interface Payable method that was
33 // abstract in superclass Employee
34 @Override
35 public double getPaymentAmount()
36 {
37     return getWeeklySalary();
38 } // end method getPaymentAmount
39
40 // return String representation of SalariedEmployee object
41 @Override
42 public String toString()
43 {
44     return String.format( "salaried employee: %s\n%s: $%,.2f",
45         super.toString(), "weekly salary", getWeeklySalary() );
46 } // end method toString
47 } // end class SalariedEmployee

```

**Fig. 10.14** | SalariedEmployee class that implements interface Payable method getPaymentAmount. (Part 2 of 2.)

### 10.7.6 Using Interface Payable to Process Invoices and Employees Polymorphically

PayableInterfaceTest (Fig. 10.15) illustrates that interface Payable can be used to process a set of Invoices and Employees polymorphically in a single application. Line 9 declares payableObjects and assigns it an array of four Payable variables. Lines 12–13 assign the references of Invoice objects to the first two elements of payableObjects. Lines 14–17 then assign the references of SalariedEmployee objects to the remaining two elements of payableObjects. These assignments are allowed because an Invoice *is a* Payable, a SalariedEmployee *is an* Employee and an Employee *is a* Payable. Lines 23–29 use the enhanced for statement to polymorphically process each Payable object in payableObjects, printing the object as a String, along with the payment amount due. Line 27

invokes method `toString` via a `Payable` interface reference, even though `toString` is not declared in interface `Payable`—*all references (including those of interface types) refer to objects that extend `Object` and therefore have a `toString` method.* (Method `toString` also can be invoked *implicitly* here.) Line 28 invokes `Payable` method `getPaymentAmount` to obtain the payment amount for each object in `payableObjects`, regardless of the actual type of the object. The output reveals that the method calls in lines 27–28 invoke the appropriate class’s implementation of methods `toString` and `getPaymentAmount`. For instance, when `currentPayable` refers to an `Invoice` during the first iteration of the `for` loop, class `Invoice`’s `toString` and `getPaymentAmount` execute.

```

1 // Fig. 10.15: PayableInterfaceTest.java
2 // Tests interface Payable.
3
4 public class PayableInterfaceTest
5 {
6     public static void main( String[] args )
7     {
8         // create four-element Payable array
9         Payable[] payableObjects = new Payable[ 4 ];
10
11        // populate array with objects that implement Payable
12        payableObjects[ 0 ] = new Invoice( "01234", "seat", 2, 375.00 );
13        payableObjects[ 1 ] = new Invoice( "56789", "tire", 4, 79.95 );
14        payableObjects[ 2 ] =
15            new SalariedEmployee( "John", "Smith", "111-11-1111", 800.00 );
16        payableObjects[ 3 ] =
17            new SalariedEmployee( "Lisa", "Barnes", "888-88-8888", 1200.00 );
18
19        System.out.println(
20            "Invoices and Employees processed polymorphically:\n" );
21
22        // generically process each element in array payableObjects
23        for ( Payable currentPayable : payableObjects )
24        {
25            // output currentPayable and its appropriate payment amount
26            System.out.printf( "%s \n%s: $%,.2f\n\n",
27                currentPayable.toString(),
28                "payment due", currentPayable.getPaymentAmount() );
29        } // end for
30    } // end main
31 } // end class PayableInterfaceTest

```

Invoices and Employees processed polymorphically:

```

invoice:
part number: 01234 (seat)
quantity: 2
price per item: $375.00
payment due: $750.00

```

**Fig. 10.15** | `Payable` interface test program processing `Invoices` and `Employees` polymorphically. (Part I of 2.)

```

invoice:
part number: 56789 (tire)
quantity: 4
price per item: $79.95
payment due: $319.80

salaried employee: John Smith
social security number: 111-11-1111
weekly salary: $800.00
payment due: $800.00

salaried employee: Lisa Barnes
social security number: 888-88-8888
weekly salary: $1,200.00
payment due: $1,200.00

```

**Fig. 10.15** | Payable interface test program processing Invoices and Employees polymorphically. (Part 2 of 2.)

### 10.7.7 Common Interfaces of the Java API

In this section, we overview several common interfaces found in the Java API. The power and flexibility of interfaces is used frequently throughout the Java API. These interfaces are implemented and used in the same manner as the interfaces you create (e.g., interface `Payable` in Section 10.7.2). The Java API's interfaces enable you to use your own classes within the frameworks provided by Java, such as comparing objects of your own types and creating tasks that can execute concurrently with other tasks in the same program. Figure 10.16 overviews a few of the more popular interfaces of the Java API that we use in *Java How to Program, Ninth Edition*.

| Interface                 | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|---------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>Comparable</code>   | Java contains several comparison operators (e.g., <code>&lt;</code> , <code>&lt;=</code> , <code>&gt;</code> , <code>&gt;=</code> , <code>==</code> , <code>!=</code> ) that allow you to compare primitive values. However, these operators <i>cannot</i> be used to compare objects. Interface <code>Comparable</code> is used to allow objects of a class that implements the interface to be compared to one another. Interface <code>Comparable</code> is commonly used for ordering objects in a collection such as an array. We use <code>Comparable</code> in Chapter 20, Generic Collections, and Chapter 21, Generic Classes and Methods. |
| <code>Serializable</code> | An interface used to identify classes whose objects can be written to (i.e., serialized) or read from (i.e., deserialized) some type of storage (e.g., file on disk, database field) or transmitted across a network. We use <code>Serializable</code> in Chapter 17, Files, Streams and Object Serialization, and Chapter 27, Networking.                                                                                                                                                                                                                                                                                                          |
| <code>Runnable</code>     | Implemented by any class for which objects of that class should be able to execute in parallel using a technique called multithreading (discussed in Chapter 26, Multithreading). The interface contains one method, <code>run</code> , which describes the behavior of an object when executed.                                                                                                                                                                                                                                                                                                                                                    |

**Fig. 10.16** | Common interfaces of the Java API. (Part 1 of 2.)

| Interface                     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| GUI event-listener interfaces | You work with graphical user interfaces (GUIs) every day. In your web browser, you might type the address of a website to visit, or you might click a button to return to a previous site. The browser responds to your interaction and performs the desired task. Your interaction is known as an event, and the code that the browser uses to respond to an event is known as an event handler. In Chapter 14, GUI Components: Part 1, and Chapter 25, GUI Components: Part 2, you'll learn how to build GUIs and event handlers that respond to user interactions. Event handlers are declared in classes that implement an appropriate event-listener interface. Each event-listener interface specifies one or more methods that must be implemented to respond to user interactions. |
| SwingConstants                | Contains a set of constants used in GUI programming to position GUI elements on the screen. We explore GUI programming in Chapters 14 and 25.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |

## 10.8 (Optional) GUI and Graphics Case Study: Drawing with Polymorphism

You may have noticed in the drawing program created in GUI and Graphics Case Study Exercise 8.1 (and modified in GUI and Graphics Case Study Exercise 9.1) that shape classes have many similarities. Using inheritance, we can “factor out” the common features from all three classes and place them in a single shape superclass. Then, using variables of the superclass type, we can manipulate shape objects polymorphically. Removing the redundant code will result in a smaller, more flexible program that’s easier to maintain.

### *GUI and Graphics Case Study Exercises*

**10.1** Modify the `MyLine`, `MyOval` and `MyRectangle` classes of GUI and Graphics Case Study Exercise 8.1 and Exercise 9.1 to create the class hierarchy in Fig. 10.17. Classes of the `MyShape` hierarchy should be “smart” shape classes that know how to draw themselves (if provided with a `Graphics` object that tells them where to draw). Once the program creates an object from this hierarchy, it can manipulate it polymorphically for the rest of its lifetime as a `MyShape`.

In your solution, class `MyShape` in Fig. 10.17 *must* be abstract. Since `MyShape` represents any shape in general, you cannot implement a `draw` method without knowing exactly what shape it is. The data representing the coordinates and color of the shapes in the hierarchy should be declared as `private` members of class `MyShape`. In addition to the common data, class `MyShape` should declare the following methods:

- A no-argument constructor that sets all the coordinates of the shape to 0 and the color to `Color.BLACK`.
- A constructor that initializes the coordinates and color to the values of the arguments supplied.
- Set* methods for the individual coordinates and color that allow the programmer to set any piece of data independently for a shape in the hierarchy.
- Get* methods for the individual coordinates and color that allow the programmer to retrieve any piece of data independently for a shape in the hierarchy.

**Fig. 10.17** | MyShape hierarchy.

e) The abstract method

```
public abstract void draw( Graphics g );
```

which the program's `paintComponent` method will call to draw a shape on the screen.

To ensure proper encapsulation, all data in class `MyShape` must be private. This requires declaring proper *set* and *get* methods to manipulate the data. Class `MyLine` should provide a no-argument constructor and a constructor with arguments for the coordinates and color. Classes `MyOval` and `MyRectangle` should provide a no-argument constructor and a constructor with arguments for the coordinates, color and determining whether the shape is filled. The no-argument constructor should, in addition to setting the default values, set the shape to be an unfilled shape.

You can draw lines, rectangles and ovals if you know two points in space. Lines require  $x1$ ,  $y1$ ,  $x2$  and  $y2$  coordinates. The `drawLine` method of the `Graphics` class will connect the two points supplied with a line. If you have the same four coordinate values ( $x1$ ,  $y1$ ,  $x2$  and  $y2$ ) for ovals and rectangles, you can calculate the four arguments needed to draw them. Each requires an upper-left  $x$ -coordinate value (the smaller of the two  $x$ -coordinate values), an upper-left  $y$ -coordinate value (the smaller of the two  $y$ -coordinate values), a *width* (the absolute value of the difference between the two  $x$ -coordinate values) and a *height* (the absolute value of the difference between the two  $y$ -coordinate values). Rectangles and ovals should also have a `filled` flag that determines whether to draw the shape as a filled shape.

There should be no `MyLine`, `MyOval` or `MyRectangle` variables in the program—only `MyShape` variables that contain references to `MyLine`, `MyOval` and `MyRectangle` objects. The program should generate random shapes and store them in an array of type `MyShape`. Method `paintComponent` should walk through the `MyShape` array and draw every shape (i.e., polymorphically calling every shape's `draw` method).

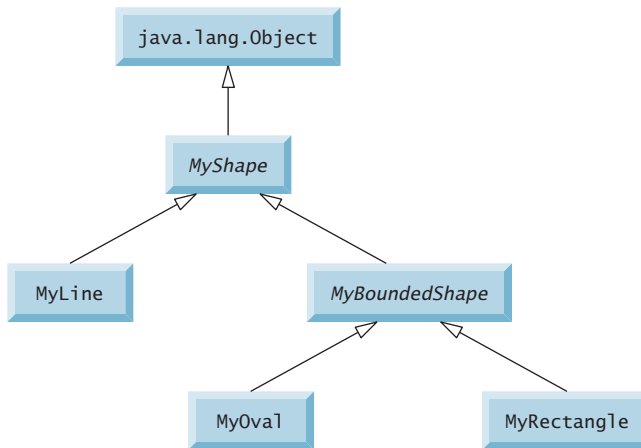

Allow the user to specify (via an input dialog) the number of shapes to generate. The program will then generate and display the shapes along with a status bar that informs the user how many of each shape were created.

**10.2 (Drawing Application Modification)** In Exercise 10.1, you created a `MyShape` hierarchy in which classes `MyLine`, `MyOval` and `MyRectangle` extend `MyShape` directly. If your hierarchy was properly designed, you should be able to see the similarities between the `MyOval` and `MyRectangle` classes. Redesign and reimplement the code for the `MyOval` and `MyRectangle` classes to “factor out” the common features into the abstract class `MyBoundedShape` to produce the hierarchy in Fig. 10.18.

Class `MyBoundedShape` should declare two constructors that mimic those of class `MyShape`, only with an added parameter to set whether the shape is filled. Class `MyBoundedShape` should also declare *get* and *set* methods for manipulating the filled flag and methods that calculate the upper-left  $x$ -coordinate, upper-left  $y$ -coordinate, width and height. Remember, the values needed to draw

an oval or a rectangle can be calculated from two  $(x, y)$  coordinates. If designed properly, the new `MyOval` and `MyRectangle` classes should each have two constructors and a `draw` method.

**Fig. 10.18** | `MyShape` hierarchy with `MyBoundedShape`.

## 10.9 Wrap-Up

This chapter introduced polymorphism—the ability to process objects that share the same superclass in a class hierarchy as if they’re all objects of the superclass. The chapter discussed how polymorphism makes systems extensible and maintainable, then demonstrated how to use overridden methods to effect polymorphic behavior. We introduced abstract classes, which allow you to provide an appropriate superclass from which other classes can inherit. You learned that an abstract class can declare abstract methods that each subclass must implement to become a concrete class and that a program can use variables of an abstract class to invoke the subclasses’ implementations of abstract methods polymorphically. You also learned how to determine an object’s type at execution time. We discussed the concepts of `final` methods and classes. Finally, the chapter discussed declaring and implementing an interface as another way to achieve polymorphic behavior.

You should now be familiar with classes, objects, encapsulation, inheritance, interfaces and polymorphism—the most essential aspects of object-oriented programming.

In the next chapter, you’ll learn about exceptions, useful for handling errors during a program’s execution. Exception handling provides for more robust programs.

## Summary

### Section 10.1 Introduction

- Polymorphism (p. 395) enables us to write programs that process objects that share the same superclass as if they’re all objects of the superclass; this can simplify programming.
- With polymorphism, we can design and implement systems that are easily extensible. The only parts of a program that must be altered to accommodate new classes are those that require direct knowledge of the new classes that you add to the hierarchy.

### Section 10.3 Demonstrating Polymorphic Behavior

- When the compiler encounters a method call made through a variable, the compiler determines if the method can be called by checking the variable's class type. If that class contains the proper method declaration (or inherits one), the call is compiled. At execution time, the type of the object to which the variable refers determines the actual method to use.

### Section 10.4 Abstract Classes and Methods

- Abstract classes (p. 400) cannot be used to instantiate objects, because they're incomplete.
- The primary purpose of an abstract class is to provide an appropriate superclass from which other classes can inherit and thus share a common design.
- Classes that can be used to instantiate objects are called concrete classes (p. 401). They provide implementations of every method they declare (some of the implementations can be inherited).
- Programmers often write client code that uses only abstract superclasses (p. 401) to reduce client code's dependencies on specific subclass types.
- Abstract classes sometimes constitute several levels of a hierarchy.
- An abstract class normally contains one or more abstract methods (p. 401).
- Abstract methods do not provide implementations.
- A class that contains any abstract methods must be declared as an abstract class (p. 401). Each concrete subclass must provide implementations of each of the superclass's abstract methods.
- Constructors and `static` methods cannot be declared abstract.
- Abstract superclass variables can hold references to objects of any concrete class derived from the superclass. Programs typically use such variables to manipulate subclass objects polymorphically.
- Polymorphism is particularly effective for implementing layered software systems.

### Section 10.5 Case Study: Payroll System Using Polymorphism

- A hierarchy designer can demand that each concrete subclass provide an appropriate method implementation by including an abstract method in a superclass.
- Most method calls are resolved at execution time, based on the type of the object being manipulated. This process is known as dynamic binding (p. 416) or late binding.
- A superclass variable can be used to invoke only methods declared in the superclass.
- Operator `instanceof` (p. 416) determines if an object has the *is-a* relationship with a specific type.
- Every object in Java knows its own class and can access it through `Object` method `getClass` (p. 417), which returns an object of type `Class` (package `java.lang`).
- The *is-a* relationship applies only between the subclass and its superclasses, not vice versa.

### Section 10.6 `final` Methods and Classes

- A method that's declared `final` (p. 418) in a superclass cannot be overridden in a subclass.
- Methods declared `private` are implicitly `final`, because you can't override them in a subclass.
- Methods that are declared `static` are implicitly `final`.
- A `final` method's declaration can never change, so all subclasses use the same implementation, and calls to `final` methods are resolved at compile time—this is known as static binding (p. 419).
- Since the compiler knows that `final` methods cannot be overridden, it can optimize programs by removing calls to `final` methods and replacing them with the expanded code of their declarations at each method-call location—a technique known as inlining the code.
- A class that's declared `final` cannot be a superclass (p. 419).
- All methods in a `final` class are implicitly `final`.

### Section 10.7 Case Study: Creating and Using Interfaces

- An interface (p. 419) specifies *what* operations are allowed but not *how* they're performed.
- A Java interface describes a set of methods that can be called on an object.
- An interface declaration begins with the keyword `interface` (p. 420).
- All interface members must be `public`, and interfaces may not specify any implementation details, such as concrete method declarations and instance variables.
- All methods declared in an interface are implicitly `public` abstract methods and all fields are implicitly `public`, `static` and `final`.
- To use an interface, a concrete class must specify that it `implements` (p. 420) the interface and must declare each interface method with the signature specified in the interface declaration. A class that does not implement all the interface's methods must be declared `abstract`.
- Implementing an interface is like signing a contract with the compiler that states, "I will declare all the methods specified by the interface or I will declare my class `abstract`."
- An interface is typically used when disparate (i.e., unrelated) classes need to share common methods and constants. This allows objects of unrelated classes to be processed polymorphically—objects of classes that implement the same interface can respond to the same method calls.
- You can create an interface that describes the desired functionality, then implement the interface in any classes that require that functionality.
- An interface is often used in place of an abstract class when there's no default implementation to inherit—that is, no instance variables and no default method implementations.
- Like `public` abstract classes, interfaces are typically `public` types, so they're normally declared in files by themselves with the same name as the interface and the `.java` file-name extension.
- Java does not allow subclasses to inherit from more than one superclass, but it does allow a class to inherit from a superclass and implement more than one interface.
- All objects of a class that implement multiple interfaces have the *is-a* relationship with each implemented interface type.
- An interface can declare constants. The constants are implicitly `public`, `static` and `final`.

## Self-Review Exercises

- 10.1** Fill in the blanks in each of the following statements:
- If a class contains at least one abstract method, it's a(n) \_\_\_\_\_ class.
  - Classes from which objects can be instantiated are called \_\_\_\_\_ classes.
  - \_\_\_\_\_ involves using a superclass variable to invoke methods on superclass and subclass objects, enabling you to "program in the general."
  - Methods that are not interface methods and that do not provide implementations must be declared using keyword \_\_\_\_\_.
  - Casting a reference stored in a superclass variable to a subclass type is called \_\_\_\_\_.
- 10.2** State whether each of the statements that follows is *true* or *false*. If *false*, explain why.
- All methods in an abstract class must be declared as abstract methods.
  - Invoking a subclass-only method through a subclass variable is not allowed.
  - If a superclass declares an abstract method, a subclass must implement that method.
  - An object of a class that implements an interface may be thought of as an object of that interface type.

## Answers to Self-Review Exercises

- 10.1** a) abstract. b) concrete. c) Polymorphism. d) abstract. e) downcasting.

- 10.2** a) False. An abstract class can include methods with implementations and abstract methods. b) False. Trying to invoke a subclass-only method with a superclass variable is not allowed. c) False. Only a concrete subclass must implement the method. d) True.

## Exercises

**10.3** How does polymorphism enable you to program “in the general” rather than “in the specific”? Discuss the key advantages of programming “in the general.”

**10.4** What are abstract methods? Describe the circumstances in which an abstract method would be appropriate.

**10.5** How does polymorphism promote extensibility?

**10.6** Discuss four ways in which you can assign superclass and subclass references to variables of superclass and subclass types.

**10.7** Compare and contrast abstract classes and interfaces. Why would you use an abstract class? Why would you use an interface?

**10.8** (*Payroll System Modification*) Modify the payroll system of Figs. 10.4–10.9 to include private instance variable `birthDate` in class `Employee`. Use class `Date` of Fig. 8.7 to represent an employee’s birthday. Add *get* methods to class `Date`. Assume that payroll is processed once per month. Create an array of `Employee` variables to store references to the various employee objects. In a loop, calculate the payroll for each `Employee` (polymorphically), and add a \$100.00 bonus to the person’s payroll amount if the current month is the one in which the `Employee`’s birthday occurs.

**10.9** (*Project: Shape Hierarchy*) Implement the Shape hierarchy shown in Fig. 9.3. Each `TwoDimensionalShape` should contain method `getArea` to calculate the area of the two-dimensional shape. Each `ThreeDimensionalShape` should have methods `getArea` and `getVolume` to calculate the surface area and volume, respectively, of the three-dimensional shape. Create a program that uses an array of `Shape` references to objects of each concrete class in the hierarchy. The program should print a text description of the object to which each array element refers. Also, in the loop that processes all the shapes in the array, determine whether each shape is a `TwoDimensionalShape` or a `ThreeDimensionalShape`. If it’s a `TwoDimensionalShape`, display its area. If it’s a `ThreeDimensionalShape`, display its area and volume.

**10.10** (*Payroll System Modification*) Modify the payroll system of Figs. 10.4–10.9 to include an additional `Employee` subclass `PieceWorker` that represents an employee whose pay is based on the number of pieces of merchandise produced. Class `PieceWorker` should contain private instance variables `wage` (to store the employee’s wage per piece) and `pieces` (to store the number of pieces produced). Provide a concrete implementation of method `earnings` in class `PieceWorker` that calculates the employee’s earnings by multiplying the number of pieces produced by the wage per piece. Create an array of `Employee` variables to store references to objects of each concrete class in the new `Employee` hierarchy. For each `Employee`, display its `String` representation and earnings.

**10.11** (*Accounts Payable System Modification*) In this exercise, we modify the accounts payable application of Figs. 10.11–10.15 to include the complete functionality of the payroll application of Figs. 10.4–10.9. The application should still process two `Invoice` objects, but now should process one object of each of the four `Employee` subclasses. If the object currently being processed is a `BasePlusCommissionEmployee`, the application should increase the `BasePlusCommissionEmployee`’s base salary by 10%. Finally, the application should output the payment amount for each object. Complete the following steps to create the new application:

- a) Modify classes `HourlyEmployee` (Fig. 10.6) and `CommissionEmployee` (Fig. 10.7) to place them in the `Payable` hierarchy as subclasses of the version of `Employee` (Fig. 10.13) that implements `Payable`. [*Hint*: Change the name of method `earnings` to `getPaymentAmount` in each subclass so that the class satisfies its inherited contract with interface `Payable`.]

- b) Modify class `BasePlusCommissionEmployee` (Fig. 10.8) such that it extends the version of class `CommissionEmployee` created in part (a).
- c) Modify `PayableInterfaceTest` (Fig. 10.15) to polymorphically process two `Invoices`, one `SalariedEmployee`, one `HourlyEmployee`, one `CommissionEmployee` and one `BasePlusCommissionEmployee`. First output a `String` representation of each `Payable` object. Next, if an object is a `BasePlusCommissionEmployee`, increase its base salary by 10%. Finally, output the payment amount for each `Payable` object.

**10.12 (Accounts Payable System Modification)** It's possible to include the functionality of the payroll application (Figs. 10.4–10.9) in the accounts payable application without modifying `Employee` subclasses `SalariedEmployee`, `HourlyEmployee`, `CommissionEmployee` or `BasePlusCommissionEmployee`. To do so, you can modify class `Employee` (Fig. 10.4) to implement interface `Payable` and declare method `getPaymentAmount` to invoke method `earnings`. Method `getPaymentAmount` would then be inherited by the subclasses in the `Employee` hierarchy. When `getPaymentAmount` is called for a particular subclass object, it polymorphically invokes the appropriate `earnings` method for that subclass. Reimplement Exercise 10.11 using the original `Employee` hierarchy from the payroll application of Figs. 10.4–10.9. Modify class `Employee` as described in this exercise, and *do not* modify any of class `Employee`'s subclasses.

## Making a Difference

**10.13 (CarbonFootprint Interface: Polymorphism)** Using interfaces, as you learned in this chapter, you can specify similar behaviors for possibly disparate classes. Governments and companies worldwide are becoming increasingly concerned with carbon footprints (annual releases of carbon dioxide into the atmosphere) from buildings burning various types of fuels for heat, vehicles burning fuels for power, and the like. Many scientists blame these greenhouse gases for the phenomenon called global warming. Create three small classes unrelated by inheritance—classes `Building`, `Car` and `Bicycle`. Give each class some unique appropriate attributes and behaviors that it does not have in common with other classes. Write an interface `CarbonFootprint` with a `getCarbonFootprint` method. Have each of your classes implement that interface, so that its `getCarbonFootprint` method calculates an appropriate carbon footprint for that class (check out a few websites that explain how to calculate carbon footprints). Write an application that creates objects of each of the three classes, places references to those objects in `ArrayList<CarbonFootprint>`, then iterates through the `ArrayList`, polymorphically invoking each object's `getCarbonFootprint` method. For each object, print some identifying information and the object's carbon footprint.

# 11

## Exception Handling: A Deeper Look

*It is common sense to take a method and try it. If it fails, admit it frankly and try another. But above all, try something.*

—Franklin Delano Roosevelt

*O! throw away the  
worse part of it,  
And live the purer  
with the other half.*

—William Shakespeare

*If they're running and they don't  
look where they're going  
I have to come out from  
somewhere and catch them.*

—Jerome David Salinger

### Objectives

In this chapter you'll learn:

- What exceptions are and how they're handled.
- When to use exception handling.
- To use `try` blocks to delimit code in which exceptions might occur.
- To `throw` exceptions to indicate a problem.
- To use `catch` blocks to specify exception handlers.
- To use the `finally` block to release resources.
- The exception class hierarchy.
- To create user-defined exceptions.

Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises

## 11.1 Introduction

As you know from Chapter 7, an exception is an indication of a problem that occurs during a program's execution. Exception handling enables you to create applications that can resolve (or handle) exceptions. In many cases, handling an exception allows a program to continue executing as if no problem had been encountered. The features presented in this chapter help you write robust and fault-tolerant programs that can deal with problems and continue executing or terminate gracefully. Java exception handling is based in part on the work of Andrew Koenig and Bjarne Stroustrup.<sup>1</sup>

First, we demonstrate basic exception-handling techniques by handling an exception that occurs when a method attempts to divide an integer by zero. Next, we introduce several classes at the top of Java's exception-handling class hierarchy. As you'll see, only classes that extend `Throwable` (package `java.lang`) directly or indirectly can be used with exception handling. We then show how to use chained exceptions. When you invoke a method that indicates an exception, you can throw another exception and chain the original one to the new one—this enables you to add application-specific information to the original exception. Next, we introduce preconditions and postconditions, which must be true when your methods are called and when they return, respectively. We then present assertions, which you can use at development time to help debug your code. Finally, we introduce two new Java SE 7 exception-handling features—catching multiple exceptions with one catch handler and the new `try-with-resources` statement that automatically releases a resource after it's used in the `try` block.

## 11.2 Example: Divide by Zero without Exception Handling

First we demonstrate what happens when errors arise in an application that does not use exception handling. Figure 11.1 prompts the user for two integers and passes them to method `quotient`, which calculates the integer quotient and returns an `int` result. In this

1. A. Koenig and B. Stroustrup, "Exception Handling for C++ (revised)," *Proceedings of the Usenix C++ Conference*, pp. 149–176, San Francisco, April 1990.

example, you'll see that exceptions are **thrown** (i.e., the exception occurs) when a method detects a problem and is unable to handle it.

```

1 // Fig. 11.1: DivideByZeroNoExceptionHandling.java
2 // Integer division without exception handling.
3 import java.util.Scanner;
4
5 public class DivideByZeroNoExceptionHandling
6 {
7     // demonstrates throwing an exception when a divide-by-zero occurs
8     public static int quotient( int numerator, int denominator )
9     {
10        return numerator / denominator; // possible division by zero
11    } // end method quotient
12
13    public static void main( String[] args )
14    {
15        Scanner scanner = new Scanner( System.in ); // scanner for input
16
17        System.out.print( "Please enter an integer numerator: " );
18        int numerator = scanner.nextInt();
19        System.out.print( "Please enter an integer denominator: " );
20        int denominator = scanner.nextInt();
21
22        int result = quotient( numerator, denominator );
23        System.out.printf(
24            "\nResult: %d / %d = %d\n", numerator, denominator, result );
25    } // end main
26 } // end class DivideByZeroNoExceptionHandling

```

**Fig. 11.1** | Integer division without exception handling.

The first sample execution in Fig. 11.1 shows a successful division. In the second execution, the user enters the value 0 as the denominator. Several lines of information are displayed in response to this invalid input. This information is known as a **stack trace**, which includes the name of the exception (`java.lang.ArithmeticException`) in a descriptive message that indicates the problem that occurred and the method-call stack (i.e., the call chain) at the time it occurred. The stack trace includes the path of execution that led to the exception method by method. This helps you debug the program. The first line specifies that an `ArithmeticException` has occurred. The text after the name of the exception (“/ by zero”) indicates that this exception occurred as a result of an attempt to divide by zero. Java *does not* allow division by zero in integer arithmetic. When this occurs, Java throws an **ArithmeticException**. `ArithmeticExceptions` can arise from a number of different problems in arithmetic, so the extra data (“/ by zero”) provides more specific information. Java *does* allow division by zero with floating-point values. Such a calculation results in the value positive or negative infinity, which is represented in Java as a floating-point value (but displays as the string `Infinity` or `-Infinity`). If 0.0 is divided by 0.0, the result is NaN (not a number), which is also represented in Java as a floating-point value (but displays as `NaN`).

Starting from the last line of the stack trace, we see that the exception was detected in line 22 of method `main`. Each line of the stack trace contains the class name and method (`DivideByZeroNoExceptionHandling.main`) followed by the file name and line number (`DivideByZeroNoExceptionHandling.java:22`). Moving up the stack trace, we see that the exception occurs in line 10, in method `quotient`. The top row of the call chain indicates the **throw point**—the initial point at which the exception occurs. The throw point of this exception is in line 10 of method `quotient`.

In the third execution, the user enters the string “hello” as the denominator. Notice again that a stack trace is displayed. This informs us that an `InputMismatchException` has occurred (package `java.util`). Our prior examples that read numeric values from the user assumed that the user would input a proper integer value. However, users sometimes make mistakes and input noninteger values. An **InputMismatchException** occurs when `Scanner` method `nextInt` receives a `string` that does not represent a valid integer. Starting from the end of the stack trace, we see that the exception was detected in line 20 of method `main`. Moving up the stack trace, we see that the exception occurred in method `nextInt`. Notice that in place of the file name and line number, we’re provided with the text `Unknown Source`. This means that the so-called debugging symbols that provide the file-name and line number information for that method’s class were not available to the JVM—this is typically the case for the classes of the Java API. Many IDEs have access to the Java API source code and will display file names and line numbers in stack traces.

In the sample executions of Fig. 11.1 when exceptions occur and stack traces are displayed, the program also exits. This does not always occur in Java—sometimes a program may continue even though an exception has occurred and a stack trace has been printed. In such cases, the application may produce unexpected results. For example, a graphical user interface (GUI) application will often continue executing. The next section demonstrates how to handle these exceptions.

In Fig. 11.1 both types of exceptions were detected in method `main`. In the next example, we’ll see how to handle these exceptions to enable the program to run to normal completion.

## 11.3 Example: Handling ArithmeticExceptions and InputMismatchExceptions

The application in Fig. 11.2, which is based on Fig. 11.1, uses exception handling to process any ArithmeticExceptions and InputMismatchExceptions that arise. The application still prompts the user for two integers and passes them to method quotient, which calculates the quotient and returns an int result. This version of the application uses exception handling so that if the user makes a mistake, the program catches and handles (i.e., deals with) the exception—in this case, allowing the user to enter the input again.

```

1 // Fig. 11.2: DivideByZeroWithExceptionHandling.java
2 // Handling ArithmeticExceptions and InputMismatchExceptions.
3 import java.util.InputMismatchException;
4 import java.util.Scanner;
5
6 public class DivideByZeroWithExceptionHandling
7 {
8     // demonstrates throwing an exception when a divide-by-zero occurs
9     public static int quotient( int numerator, int denominator )
10    throws ArithmeticException
11    {
12        return numerator / denominator; // possible division by zero
13    } // end method quotient
14
15    public static void main( String[] args )
16    {
17        Scanner scanner = new Scanner( System.in ); // scanner for input
18        boolean continueLoop = true; // determines if more input is needed
19
20        do
21        {
22            try // read two numbers and calculate quotient
23            {
24                System.out.print( "Please enter an integer numerator: " );
25                int numerator = scanner.nextInt();
26                System.out.print( "Please enter an integer denominator: " );
27                int denominator = scanner.nextInt();
28
29                int result = quotient( numerator, denominator );
30                System.out.printf( "\nResult: %d / %d = %d\n", numerator,
31                                denominator, result );
32                continueLoop = false; // input successful; end looping
33            } // end try
34            catch ( InputMismatchException inputMismatchException )
35            {
36                System.err.printf( "\nException: %s\n",
37                                inputMismatchException );
38                scanner.nextLine(); // discard input so user can try again
39                System.out.println(
40                    "You must enter integers. Please try again.\n" );
41            } // end catch

```

**Fig. 11.2** | Handling ArithmeticExceptions and InputMismatchExceptions. (Part I of 2.)

```

42     catch ( ArithmeticException arithmeticException )
43     {
44         System.err.printf( "\nException: %s\n", arithmeticException );
45         System.out.println(
46             "Zero is an invalid denominator. Please try again.\n" );
47     } // end catch
48 } while ( continueLoop ); // end do...while
49 } // end main
50 } // end class DivideByZeroWithExceptionHandling

```

Please enter an integer numerator: **100**

Please enter an integer denominator: **7**

Exception: java.util.InputMismatchException  
You must enter integers. Please try again.

Please enter an integer numerator: **100**

Please enter an integer denominator: **7**

Result: 100 / 7 = 14

**Fig. 11.2** | Handling ArithmeticExceptions and InputMismatchExceptions. (Part 2 of 2.)

The first sample execution in Fig. 11.2 is a successful one that does not encounter any problems. In the second execution the user enters a zero denominator, and an `ArithmeticException` exception occurs. In the third execution the user enters the string "hello" as the denominator, and an `InputMismatchException` occurs. For each exception, the user is informed of the mistake and asked to try again, then is prompted for two new integers. In each sample execution, the program runs successfully to completion.

Class `InputMismatchException` is imported in line 3. Class `ArithmeticException` does not need to be imported because it's in package `java.lang`. Line 18 creates the boolean variable `continueLoop`, which is true if the user has not yet entered valid input. Lines 20–48 repeatedly ask users for input until a valid input is received.

### Enclosing Code in a try Block

Lines 22–33 contain a **try block**, which encloses the code that might throw an exception and the code that should not execute if an exception occurs (i.e., if an exception occurs, the remaining code in the try block will be skipped). A try block consists of the keyword `try` followed by a block of code enclosed in curly braces. [Note: The term “try block” sometimes refers only to the block of code that follows the try keyword (not including the try keyword itself). For simplicity, we use the term “try block” to refer to the block of code that follows the try keyword, as well as the try keyword.] The statements that read the integers from the keyboard (lines 25 and 27) each use method `nextInt` to read an `int` value. Method `nextInt` throws an `InputMismatchException` if the value read in is not an integer.

The division that can cause an `ArithmeticException` is not performed in the try block. Rather, the call to method `quotient` (line 29) invokes the code that attempts the division (line 12); the JVM throws an `ArithmeticException` object when the denominator is zero.

### Software Engineering Observation 11.1

Exceptions may surface through explicitly mentioned code in a try block, through calls to other methods, through deeply nested method calls initiated by code in a try block or from the Java Virtual Machine as it executes Java bytecodes.

### Catching Exceptions

The try block in this example is followed by two catch blocks—one that handles an `InputMismatchException` (lines 34–41) and one that handles an `ArithmeticException` (lines 42–47). A **catch block** (also called a **catch clause** or **exception handler**) catches (i.e., receives) and handles an exception. A catch block begins with the keyword `catch` and is followed by a parameter in parentheses (called the exception parameter, discussed shortly) and a block of code enclosed in curly braces. [Note: The term “catch clause” is sometimes used to refer to the keyword `catch` followed by a block of code, whereas the term “catch block” refers to only the block of code following the `catch` keyword, but not including it. For simplicity, we use the term “catch block” to refer to the block of code following the `catch` keyword, as well as the keyword itself.]

At least one catch block or a **finally block** (discussed in Section 11.6) must immediately follow the try block. Each catch block specifies in parentheses an **exception parameter** that identifies the exception type the handler can process. When an exception occurs in a try block, the catch block that executes is the *first* one whose type matches the type of the exception that occurred (i.e., the type in the catch block matches the thrown exception type exactly or is a superclass of it). The exception parameter’s name enables the catch block to interact with a caught exception object—e.g., to implicitly invoke the caught exception’s `toString` method (as in lines 37 and 44), which displays basic information about the exception. Notice that we use the **System.err** (standard error stream) object to output error messages. By default, `System.err`’s print methods, like those of `System.out`, display data to the command prompt.

Line 38 of the first catch block calls Scanner method `nextLine`. Because an `InputMismatchException` occurred, the call to method `nextInt` never successfully read in the user’s data—so we read that input with a call to method `nextLine`. We do not do anything with the input at this point, because we know that it’s invalid. Each catch block displays an error message and asks the user to try again. After either catch block terminates, the

user is prompted for input. We'll soon take a deeper look at how this flow of control works in exception handling.

### Common Programming Error 11.1

*It's a syntax error to place code between a try block and its corresponding catch blocks.*

### Common Programming Error 11.2

*Each catch block can have only a single parameter—specifying a comma-separated list of exception parameters is a syntax error.*

An **uncaught exception** is one for which there are no matching catch blocks. You saw uncaught exceptions in the second and third outputs of Fig. 11.1. Recall that when exceptions occurred in that example, the application terminated early (after displaying the exception's stack trace). This does not always occur as a result of uncaught exceptions. Java uses a “multithreaded” model of program execution—each **thread** is a parallel activity. One program can have many threads. If a program has only one thread, an uncaught exception will cause the program to terminate. If a program has multiple threads, an uncaught exception will terminate *only* the thread where the exception occurred. In such programs, however, certain threads may rely on others, and if one thread terminates due to an uncaught exception, there may be adverse effects to the rest of the program. Chapter 26, Multithreading, discusses these issues in depth.

### Termination Model of Exception Handling

If an exception occurs in a try block (such as an `InputMismatchException` being thrown as a result of the code at line 25 of Fig. 11.2), the try block terminates immediately and program control transfers to the *first* of the following catch blocks in which the exception parameter's type matches the thrown exception's type. In Fig. 11.2, the first catch block catches `InputMismatchExceptions` (which occur if invalid input is entered) and the second catch block catches `ArithmeticExceptions` (which occur if an attempt is made to divide by zero). After the exception is handled, program control does *not* return to the throw point, because the try block has *expired* (and its local variables have been lost). Rather, control resumes after the last catch block. This is known as the **termination model of exception handling**. Some languages use the **resumption model of exception handling**, in which, after an exception is handled, control resumes just after the throw point.

Notice that we name our exception parameters (`inputMismatchException` and `arithmeticException`) based on their type. Java programmers often simply use the letter *e* as the name of their exception parameters.

### Good Programming Practice 11.1

*Using an exception-parameter name that reflects the parameter's type promotes clarity by reminding you of the type of exception being handled.*

After executing a catch block, this program's flow of control proceeds to the first statement after the last catch block (line 48 in this case). The condition in the `do...while` statement is true (variable `continueLoop` contains its initial value of true), so control returns to the beginning of the loop and the user is once again prompted for input. This

control statement will loop until valid input is entered. At that point, program control reaches line 32, which assigns `false` to variable `continueLoop`. The `try` block then terminates. If no exceptions are thrown in the `try` block, the `catch` blocks are skipped and control continues with the first statement after the `catch` blocks (we'll learn about another possibility when we discuss the `finally` block in Section 11.6). Now the condition for the `do...while` loop is `false`, and method `main` ends.

The `try` block and its corresponding `catch` and/or `finally` blocks form a **try statement**. Do not confuse the terms “try block” and “try statement”—the latter includes the `try` block as well as the following `catch` blocks and/or `finally` block.

As with any other block of code, when a `try` block terminates, local variables declared in the block go out of scope and are no longer accessible; thus, the local variables of a `try` block are not accessible in the corresponding `catch` blocks. When a `catch` block terminates, local variables declared within the `catch` block (including the exception parameter of that `catch` block) also go out of scope and are destroyed. Any remaining `catch` blocks in the `try` statement are ignored, and execution resumes at the first line of code after the `try...catch` sequence—this will be a `finally` block, if one is present.

### Using the `throws` Clause

Now let's examine method `quotient` (Fig. 11.2, lines 9–13). The portion of the method declaration located at line 10 is known as a **throws clause**. It specifies the exceptions the method throws. This clause appears *after* the method's parameter list and *before* the method's body. It contains a comma-separated list of the exceptions that the method will throw if various problems occur. Such exceptions may be thrown by statements in the method's body or by methods called from the body. A method can throw exceptions of the classes listed in its `throws` clause or of their subclasses. We've added the `throws` clause to this application to indicate to the rest of the program that this method may throw an `ArithmeticException`. Clients of method `quotient` are thus informed that the method may throw an `ArithmeticException`. You'll learn more about the `throws` clause in Section 11.5.

#### Error-Prevention Tip 11.1

*Read the online API documentation for a method before using it in a program. The documentation specifies the exceptions thrown by the method (if any) and indicates reasons why such exceptions may occur. Next, read the online API documentation for the specified exception classes. The documentation for an exception class typically contains potential reasons that such exceptions occur. Finally, provide for handling those exceptions in your program.*

When line 12 executes, if the denominator is zero, the JVM throws an `ArithmeticException` object. This object will be caught by the `catch` block at lines 42–47, which displays basic information about the exception by implicitly invoking the exception's `toString` method, then asks the user to try again.

If the denominator is not zero, method `quotient` performs the division and returns the result to the point of invocation of method `quotient` in the `try` block (line 29). Lines 30–31 display the result of the calculation and line 32 sets `continueLoop` to `false`. In this case, the `try` block completes successfully, so the program skips the `catch` blocks and fails the condition at line 48, and method `main` completes execution normally.

When `quotient` throws an `ArithmeticException`, `quotient` terminates and does not return a value, and `quotient`'s local variables go out of scope (and are destroyed). If quo-

tient contained local variables that were references to objects and there were no other references to those objects, the objects would be marked for garbage collection. Also, when an exception occurs, the try block from which quotient was called terminates before lines 30–32 can execute. Here, too, if local variables were created in the try block prior to the exception’s being thrown, these variables would go out of scope.

If an `InputMismatchException` is generated by lines 25 or 27, the try block terminates and execution continues with the catch block at lines 34–41. In this case, method `quotient` is not called. Then method `main` continues after the last catch block (line 48).

## 11.4 When to Use Exception Handling

Exception handling is designed to process **synchronous errors**, which occur when a statement executes. Common examples we’ll see throughout the book are out-of-range array indices, arithmetic overflow (i.e., a value outside the representable range of values), division by zero, invalid method parameters, thread interruption (as we’ll see in Chapter 26) and unsuccessful memory allocation (due to lack of memory). Exception handling is not designed to process problems associated with **asynchronous events** (e.g., disk I/O completions, network message arrivals, mouse clicks and keystrokes), which occur in parallel with, and independent of, the program’s flow of control.

### Software Engineering Observation 11.2

*Incorporate your exception-handling strategy into your system from the inception of the design process. Including exception handling after a system has been implemented can be difficult.*

### Software Engineering Observation 11.3

*Exception handling provides a single, uniform technique for processing problems. This helps programmers working on large projects understand each other’s error-processing code.*

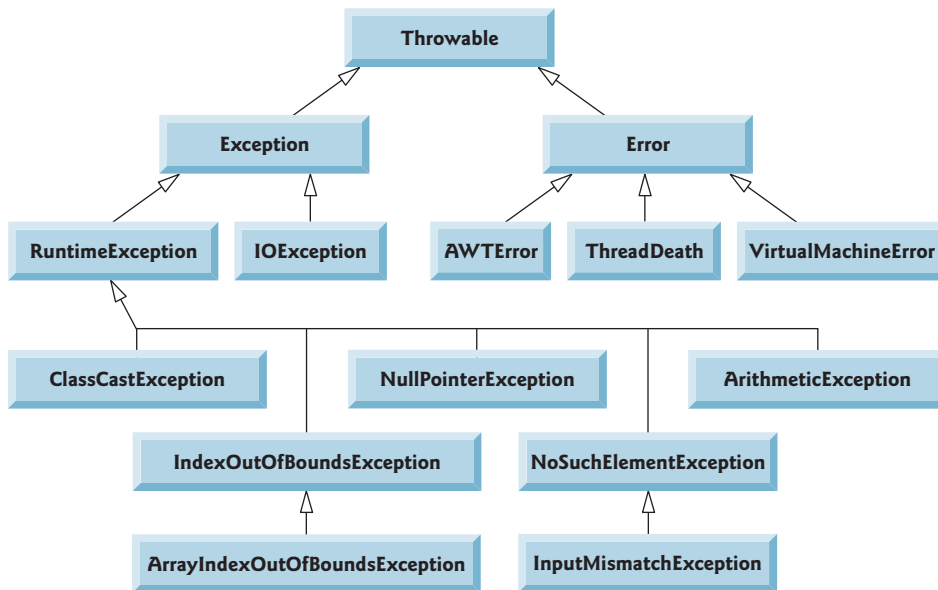

## 11.5 Java Exception Hierarchy

All Java exception classes inherit directly or indirectly from class **Exception**, forming an inheritance hierarchy. You can extend this hierarchy with your own exception classes.

Figure 11.3 shows a small portion of the inheritance hierarchy for class **Throwable** (a subclass of `Object`), which is the superclass of class `Exception`. Only `Throwable` objects can be used with the exception-handling mechanism. Class `Throwable` has two subclasses: `Exception` and `Error`. Class `Exception` and its subclasses—for instance, `RuntimeException` (package `java.lang`) and `IOException` (package `java.io`)—represent exceptional situations that can occur in a Java program and that can be caught by the application. Class **Error** and its subclasses represent abnormal situations that happen in the JVM. Most *Errors happen infrequently and should not be caught by applications—it’s usually not possible for applications to recover from Errors.*

The Java exception hierarchy contains hundreds of classes. Information about Java’s exception classes can be found throughout the Java API. You can view `Throwable`’s documentation at [download.oracle.com/javase/6/docs/api/java/lang/Throwable.html](http://download.oracle.com/javase/6/docs/api/java/lang/Throwable.html). From there, you can look at this class’s subclasses to get more information about Java’s `Exceptions` and `Errors`.

**Fig. 11.3** | Portion of class `Throwable`'s inheritance hierarchy.

### *Checked vs. Unchecked Exceptions*

Java distinguishes between **checked exceptions** and **unchecked exceptions**. This distinction is important, because the Java compiler enforces a **catch-or-declare requirement** for checked exceptions. An exception's type determines whether it's checked or unchecked. All exception types that are direct or indirect subclasses of class `RuntimeException` (package `java.lang`) are unchecked exceptions. These are typically caused by defects in your program's code. Examples of unchecked exceptions include `ArrayIndexOutOfBoundsException` (discussed in Chapter 7) and `ArithmeticException` (shown in Fig. 11.3). All classes that inherit from class `Exception` but not class `RuntimeException` are considered to be checked exceptions. Such exceptions are typically caused by conditions that are not under the control of the program—for example, in file processing, the program can't open a file because the file does not exist. Classes that inherit from class `Error` are considered to be unchecked.

The compiler *checks* each method call and method declaration to determine whether the method throws checked exceptions. If so, the compiler verifies that the checked exception is caught or is declared in a `throws` clause. We show how to catch and declare checked exceptions in the next several examples. Recall from Section 11.3 that the `throws` clause specifies the exceptions a method throws. Such exceptions are not caught in the method's body. To satisfy the *catch* part of the catch-or-declare requirement, the code that generates the exception must be wrapped in a `try` block and must provide a catch handler for the checked-exception type (or one of its superclass types). To satisfy the *declare* part of the catch-or-declare requirement, the method containing the code that generates the exception must provide a `throws` clause containing the checked-exception type after its parameter list and before its method body. If the catch-or-declare requirement is not satisfied, the compiler will issue an error message indicating that the exception must be caught or

declared. This forces you to think about the problems that may occur when a method that throws checked exceptions is called.

#### Software Engineering Observation 11.4

*You must deal with checked exceptions. This results in more robust code than would be created if you were able to simply ignore the exceptions.*

#### Common Programming Error 11.3

*A compilation error occurs if a method explicitly attempts to throw a checked exception (or calls another method that throws a checked exception) and that exception is not listed in that method's throws clause.*

#### Common Programming Error 11.4

*If a subclass method overrides a superclass method, it's an error for the subclass method to list more exceptions in its throws clause than the overridden superclass method does. However, a subclass's throws clause can contain a subset of a superclass's throws list.*

#### Software Engineering Observation 11.5

*If your method calls other methods that throw checked exceptions, those exceptions must be caught or declared in your method. If an exception can be handled meaningfully in a method, the method should catch the exception rather than declare it.*

Unlike checked exceptions, the Java compiler does *not* check the code to determine whether an unchecked exception is caught or declared. Unchecked exceptions typically can be prevented by proper coding. For example, the unchecked `ArithmeticException` thrown by method `quotient` (lines 9–13) in Fig. 11.2 can be avoided if the method ensures that the denominator is not zero *before* attempting to perform the division. Unchecked exceptions are not required to be listed in a method's throws clause—even if they are, it's not required that such exceptions be caught by an application.

#### Software Engineering Observation 11.6

*Although the compiler does not enforce the catch-or-declare requirement for unchecked exceptions, provide appropriate exception-handling code when it's known that such exceptions might occur. For example, a program should process the `NumberFormatException` from `Integer` method `parseInt`, even though `NumberFormatException` (an indirect subclass of `RuntimeException`) is an unchecked exception type. This makes your programs more robust.*

### Catching Subclass Exceptions

If a catch handler is written to catch superclass-type exception objects, it can also catch all objects of that class's subclasses. This enables catch to handle related errors with a concise notation and allows for polymorphic processing of related exceptions. You can certainly catch each subclass type individually if those exceptions require different processing.

### Only the First Matching catch Executes

If there are *multiple* catch blocks that match a particular exception type, only the *first* matching catch block executes when an exception of that type occurs. It's a compilation error to catch the *exact same type* in two different catch blocks associated with a particular try block. However, there may be several catch blocks that match an exception—i.e., sev-

eral catch blocks whose types are the same as the exception type or a superclass of that type. For instance, we could follow a catch block for type `ArithmeticException` with a catch block for type `Exception`—both would match `ArithmeticExceptions`, but only the first matching catch block would execute.

### Error-Prevention Tip 11.2

*Catching subclass types individually is subject to error if you forget to test for one or more of the subclass types explicitly; catching the superclass guarantees that objects of all subclasses will be caught. Positioning a catch block for the superclass type after all other subclass catch blocks ensures that all subclass exceptions are eventually caught.*

### Common Programming Error 11.5

*Placing a catch block for a superclass exception type before other catch blocks that catch subclass exception types would prevent those catch blocks from executing, so a compilation error occurs.*

## 11.6 finally Block

Programs that obtain certain types of resources must return them to the system explicitly to avoid so-called **resource leaks**. In programming languages such as C and C++, the most common kind of resource leak is a memory leak. Java performs automatic garbage collection of memory no longer used by programs, thus avoiding most memory leaks. However, other types of resource leaks can occur. For example, files, database connections and network connections that are not closed properly after they're no longer needed might not be available for use in other programs.

### Error-Prevention Tip 11.3

*A subtle issue is that Java does not entirely eliminate memory leaks. Java will not garbage-collect an object until there are no remaining references to it. Thus, if you erroneously keep references to unwanted objects, memory leaks can occur. To help avoid this problem, set reference-type variables to `null` when they're no longer needed.*

The `finally` block (which consists of the `finally` keyword, followed by code enclosed in curly braces), sometimes referred to as the **finally clause**, is optional. If it's present, it's placed after the last catch block. If there are no catch blocks, the `finally` block immediately follows the `try` block.

The `finally` block will execute whether or not an exception is thrown in the corresponding `try` block. The `finally` block also will execute if a `try` block exits by using a `return`, `break` or `continue` statement or simply by reaching its closing right brace. The `finally` block will *not* execute if the application exits early from a `try` block by calling method `System.exit`. This method, which we demonstrate in Chapter 17, immediately terminates an application.

Because a `finally` block almost always executes, it typically contains resource-release code. Suppose a resource is allocated in a `try` block. If no exception occurs, the catch blocks are skipped and control proceeds to the `finally` block, which frees the resource. Control then proceeds to the first statement after the `finally` block. If an exception occurs in the `try` block, the `try` block terminates. If the program catches the exception in one of the corresponding catch blocks, it processes the exception, then the `finally` block

releases the resource and control proceeds to the first statement after the finally block. If the program doesn't catch the exception, the finally block *still* releases the resource and an attempt is made to catch the exception in a calling method.

#### Error-Prevention Tip 11.4

*The finally block is an ideal place to release resources acquired in a try block (such as opened files), which helps eliminate resource leaks.*

#### Performance Tip 11.1

*Always release a resource explicitly and at the earliest possible moment at which it's no longer needed. This makes resources available for reuse as early as possible, thus improving resource utilization.*

If an exception that occurs in a try block cannot be caught by one of that try block's catch handlers, the program skips the rest of the try block and control proceeds to the finally block. Then the program passes the exception to the next outer try block—normally in the calling method—where an associated catch block might catch it. This process can occur through many levels of try blocks. Also, the exception could go uncaught.

If a catch block throws an exception, the finally block still executes. Then the exception is passed to the next outer try block—again, normally in the calling method.

Figure 11.4 demonstrates that the finally block executes even if an exception is not thrown in the corresponding try block. The program contains static methods main (lines 6–18), throwException (lines 21–44) and doesNotThrowException (lines 47–64). Methods throwException and doesNotThrowException are declared static, so main can call them directly without instantiating a UsingExceptions object.

```

1 // Fig. 11.4: UsingExceptions.java
2 // try...catch...finally exception handling mechanism.
3
4 public class UsingExceptions
5 {
6     public static void main( String[] args )
7     {
8         try
9         {
10            throwException(); // call method throwException
11        } // end try
12        catch ( Exception exception ) // exception thrown by throwException
13        {
14            System.err.println( "Exception handled in main" );
15        } // end catch
16
17        doesNotThrowException();
18    } // end main
19
20    // demonstrate try...catch...finally
21    public static void throwException() throws Exception
22    {

```

**Fig. 11.4** | try...catch...finally exception-handling mechanism. (Part I of 2.)

```

23     try // throw an exception and immediately catch it
24     {
25         System.out.println( "Method throwException" );
26         throw new Exception(); // generate exception
27     } // end try
28     catch ( Exception exception ) // catch exception thrown in try
29     {
30         System.err.println(
31             "Exception handled in method throwException" );
32         throw exception; // rethrow for further processing
33
34         // code here would not be reached; would cause compilation errors
35
36     } // end catch
37     finally // executes regardless of what occurs in try...catch
38     {
39         System.err.println( "Finally executed in throwException" );
40     } // end finally
41
42     // code here would not be reached; would cause compilation errors
43
44 } // end method throwException
45
46 // demonstrate finally when no exception occurs
47 public static void doesNotThrowException()
48 {
49     try // try block does not throw an exception
50     {
51         System.out.println( "Method doesNotThrowException" );
52     } // end try
53     catch ( Exception exception ) // does not execute
54     {
55         System.err.println( exception );
56     } // end catch
57     finally // executes regardless of what occurs in try...catch
58     {
59         System.err.println(
60             "Finally executed in doesNotThrowException" );
61     } // end finally
62
63     System.out.println( "End of method doesNotThrowException" );
64 } // end method doesNotThrowException
65 } // end class UsingExceptions

```

```

Method throwException
Exception handled in method throwException
Finally executed in throwException
Exception handled in main
Method doesNotThrowException
Finally executed in doesNotThrowException
End of method doesNotThrowException

```

**Fig. 11.4** | try...catch...finally exception-handling mechanism. (Part 2 of 2.)

`System.out` and `System.err` are **streams**—sequences of bytes. While `System.out` (known as the **standard output stream**) displays a program’s output, `System.err` (known as the **standard error stream**) displays a program’s errors. Output from these streams can be redirected (i.e., sent to somewhere other than the command prompt, such as to a file). Using two different streams enables you to easily separate error messages from other output. For instance, data output from `System.err` could be sent to a log file, while data output from `System.out` can be displayed on the screen. For simplicity, this chapter will not redirect output from `System.err`, but will display such messages to the command prompt. You’ll learn more about streams in Chapter 17.

### Throwing Exceptions Using the `throw` Statement

Method `main` (Fig. 11.4) begins executing, enters its try block and immediately calls method `throwException` (line 10). Method `throwException` throws an `Exception`. The statement at line 26 is known as a **throw statement**—it’s executed to indicate that an exception has occurred. So far, you’ve only caught exceptions thrown by called methods. You can throw exceptions yourself by using the `throw` statement. Just as with exceptions thrown by the Java API’s methods, this indicates to client applications that an error has occurred. A `throw` statement specifies an object to be thrown. The operand of a `throw` can be of any class derived from class `Throwable`.

#### Software Engineering Observation 11.7

*When `toString` is invoked on any `Throwable` object, its resulting string includes the descriptive string that was supplied to the constructor, or simply the class name if no string was supplied.*

#### Software Engineering Observation 11.8

*An object can be thrown without containing information about the problem that occurred. In this case, simply knowing that an exception of a particular type occurred may provide sufficient information for the handler to process the problem correctly.*

#### Software Engineering Observation 11.9

*Exceptions can be thrown from constructors. When an error is detected in a constructor, an exception should be thrown to avoid creating an improperly formed object.*

### Rethrowing Exceptions

Line 32 of Fig. 11.4 **rethrows the exception**. Exceptions are rethrown when a catch block, upon receiving an exception, decides either that it cannot process that exception or that it can only partially process it. Rethrowing an exception defers the exception handling (or perhaps a portion of it) to another catch block associated with an outer try statement. An exception is rethrown by using the **throw keyword**, followed by a reference to the exception object that was just caught. Exceptions cannot be rethrown from a `finally` block, as the exception parameter (a local variable) from the catch block no longer exists.

When a rethrow occurs, the *next enclosing try block* detects the rethrown exception, and that try block’s catch blocks attempt to handle it. In this case, the next enclosing try block is found at lines 8–11 in method `main`. Before the rethrown exception is handled, however, the `finally` block (lines 37–40) executes. Then method `main` detects the rethrown exception in the try block and handles it in the catch block (lines 12–15).

Next, `main` calls `methodDoesNotThrowException` (line 17). No exception is thrown in `methodDoesNotThrowException`'s `try` block (lines 49–52), so the program skips the `catch` block (lines 53–56), but the `finally` block (lines 57–61) nevertheless executes. Control proceeds to the statement after the `finally` block (line 63). Then control returns to `main` and the program terminates.

### Common Programming Error 11.6

*If an exception has not been caught when control enters a `finally` block and the `finally` block throws an exception that's not caught in the `finally` block, the first exception will be lost and the exception from the `finally` block will be returned to the calling method.*

### Error-Prevention Tip 11.5

*Avoid placing code that can throw an exception in a `finally` block. If such code is required, enclose the code in a `try...catch` within the `finally` block.*

### Common Programming Error 11.7

*Assuming that an exception thrown from a `catch` block will be processed by that `catch` block or any other `catch` block associated with the same `try` statement can lead to logic errors.*

### Good Programming Practice 11.2

*Exception handling is intended to remove error-processing code from the main line of a program's code to improve program clarity. Do not place `try...catch...finally` around every statement that may throw an exception. This makes programs difficult to read. Rather, place one `try` block around a significant portion of your code, follow that `try` block with `catch` blocks that handle each possible exception and follow the `catch` blocks with a single `finally` block (if one is required).*

## 11.7 Stack Unwinding and Obtaining Information from an Exception Object

When an exception is thrown but not caught in a particular scope, the method-call stack is “unwound,” and an attempt is made to catch the exception in the next outer `try` block. This process is called **stack unwinding**. Unwinding the method-call stack means that the method in which the exception was not caught *terminates*, all local variables in that method go out of scope and control returns to the statement that originally invoked that method. If a `try` block encloses that statement, an attempt is made to catch the exception. If a `try` block does not enclose that statement or if the exception is not caught, stack unwinding occurs again. Figure 11.5 demonstrates stack unwinding, and the exception handler in `main` shows how to access the data in an exception object.

### Stack Unwinding

In `main`, the `try` block (lines 8–11) calls `method1` (declared at lines 35–38), which in turn calls `method2` (declared at lines 41–44), which in turn calls `method3` (declared at lines 47–50). Line 49 of `method3` throws an `Exception` object—this is the *throw point*. Because the `throw` statement at line 49 is *not* enclosed in a `try` block, *stack unwinding* occurs—`method3` terminates at line 49, then returns control to the statement in `method2` that invoked `method3` (i.e., line 43). Because *no* `try` block encloses line 43, *stack unwinding* occurs

```
1 // Fig. 11.5: UsingExceptions.java
2 // Stack unwinding and obtaining data from an exception object.
3
4 public class UsingExceptions
5 {
6     public static void main( String[] args )
7     {
8         try
9         {
10            method1(); // call method1
11        } // end try
12        catch ( Exception exception ) // catch exception thrown in method1
13        {
14            System.err.printf( "%s\n\n", exception.getMessage() );
15            exception.printStackTrace(); // print exception stack trace
16
17            // obtain the stack-trace information
18            StackTraceElement[] traceElements = exception.getStackTrace();
19
20            System.out.println( "\nStack trace from getStackTrace:" );
21            System.out.println( "Class\t\tFile\t\t\tLine\tMethod" );
22
23            // loop through traceElements to get exception description
24            for ( StackTraceElement element : traceElements )
25            {
26                System.out.printf( "%s\t", element.getClassName() );
27                System.out.printf( "%s\t", element.getFileName() );
28                System.out.printf( "%s\t", element.getLineNumber() );
29                System.out.printf( "%s\n", element.getMethodName() );
30            } // end for
31        } // end catch
32    } // end main
33
34    // call method2; throw exceptions back to main
35    public static void method1() throws Exception
36    {
37        method2();
38    } // end method method1
39
40    // call method3; throw exceptions back to method1
41    public static void method2() throws Exception
42    {
43        method3();
44    } // end method method2
45
46    // throw Exception back to method2
47    public static void method3() throws Exception
48    {
49        throw new Exception( "Exception thrown in method3" );
50    } // end method method3
51 } // end class UsingExceptions
```

**Fig. 11.5** | Stack unwinding and obtaining data from an exception object. (Part 2 of 2.)

again—method2 terminates at line 43 and returns control to the statement in method1 that invoked method2 (i.e., line 37). Because *no* try block encloses line 37, *stack unwinding* occurs one more time—method1 terminates at line 37 and returns control to the statement in main that invoked method1 (i.e., line 10). The try block at lines 8–11 encloses this statement. The exception has not been handled, so the try block terminates and the first matching catch block (lines 12–31) catches and processes the exception. If there were no matching catch blocks, and the exception is not declared in each method that throws it, a compilation error would occur. Remember that this is not always the case—for *unchecked* exceptions, the application will compile, but it will run with unexpected results.

### Obtaining Data from an Exception Object

Recall that exceptions derive from class `Throwable`. Class `Throwable` offers a **`printStackTrace`** method that outputs to the standard error stream the stack trace (discussed in Section 11.2). Often, this is helpful in testing and debugging. Class `Throwable` also provides a **`getStackTrace`** method that retrieves the stack-trace information that might be printed by `printStackTrace`. Class `Throwable`'s **`getMessage`** method returns the descriptive string stored in an exception.

#### Error-Prevention Tip 11.6

*An exception that's not caught in an application causes Java's default exception handler to run. This displays the name of the exception, a descriptive message that indicates the problem that occurred and a complete execution stack trace. In an application with a single thread of execution, the application terminates. In an application with multiple threads, the thread that caused the exception terminates.*

#### Error-Prevention Tip 11.7

*`Throwable` method `toString` (inherited by all `Throwable` subclasses) returns a `String` containing the name of the exception's class and a descriptive message.*

The catch handler in Fig. 11.5 (lines 12–31) demonstrates `getMessage`, `printStackTrace` and `getStackTrace`. If we wanted to output the stack-trace information to

streams other than the standard error stream, we could use the information returned from `getStackTrace` and output it to another stream or use one of the overloaded versions of method `printStackTrace`. Sending data to other streams is discussed in Chapter 17.

Line 14 invokes the exception's `getMessage` method to get the exception description. Line 15 invokes the exception's `printStackTrace` method to output the stack trace that indicates where the exception occurred. Line 18 invokes the exception's `getStackTrace` method to obtain the stack-trace information as an array of `StacktraceElement` objects. Lines 24–30 get each `StacktraceElement` in the array and invoke its methods `getClassName`, `getFileName`, `getLineNumber` and `getMethodName` to get the class name, file name, line number and method name, respectively, for that `StacktraceElement`. Each `StacktraceElement` represents one method call on the method-call stack.

The program's output shows that the stack-trace information printed by `printStackTrace` follows the pattern: *className.methodName(fileName:lineNumber)*, where *className*, *methodName* and *fileName* indicate the names of the class, method and file in which the exception occurred, respectively, and the *lineNumber* indicates where in the file the exception occurred. You saw this in the output for Fig. 11.1. Method `getStackTrace` enables custom processing of the exception information. Compare the output of `printStackTrace` with the output created from the `StacktraceElements` to see that both contain the same stack-trace information.

### Software Engineering Observation 11.10

*Never provide a catch handler with an empty body—this effectively ignores the exception. At least use `printStackTrace` to output an error message to indicate that a problem exists.*

## 11.8 Chained Exceptions

Sometimes a method responds to an exception by throwing a different exception type that's specific to the current application. If a catch block throws a new exception, the original exception's information and stack trace are *lost*. Earlier Java versions provided no mechanism to wrap the original exception information with the new exception's information to provide a complete stack trace showing where the original problem occurred. This made debugging such problems particularly difficult. **Chained exceptions** enable an exception object to maintain the complete stack-trace information from the original exception. Figure 11.6 demonstrates chained exceptions.

```

1 // Fig. 11.6: UsingChainedExceptions.java
2 // Chained exceptions.
3
4 public class UsingChainedExceptions
5 {
6     public static void main( String[] args )
7     {
8         try
9         {
```

**Fig. 11.6** | Chained exceptions. (Part I of 2.)

```

10     method1(); // call method1
11 } // end try
12 catch ( Exception exception ) // exceptions thrown from method1
13 {
14     exception.printStackTrace();
15 } // end catch
16 } // end main
17
18 // call method2; throw exceptions back to main
19 public static void method1() throws Exception
20 {
21     try
22     {
23         method2(); // call method2
24     } // end try
25     catch ( Exception exception ) // exception thrown from method2
26     {
27         throw new Exception( "Exception thrown in method1", exception );
28     } // end catch
29 } // end method method1
30
31 // call method3; throw exceptions back to method1
32 public static void method2() throws Exception
33 {
34     try
35     {
36         method3(); // call method3
37     } // end try
38     catch ( Exception exception ) // exception thrown from method3
39     {
40         throw new Exception( "Exception thrown in method2", exception );
41     } // end catch
42 } // end method method2
43
44 // throw Exception back to method2
45 public static void method3() throws Exception
46 {
47     throw new Exception( "Exception thrown in method3" );
48 } // end method method3
49 } // end class UsingChainedExceptions

```

```

java.lang.Exception: Exception thrown in method1
    at UsingChainedExceptions.method1(UsingChainedExceptions.java:27)
    at UsingChainedExceptions.main(UsingChainedExceptions.java:10)
Caused by: java.lang.Exception: Exception thrown in method2
    at UsingChainedExceptions.method2(UsingChainedExceptions.java:40)
    at UsingChainedExceptions.method1(UsingChainedExceptions.java:23)
    ... 1 more
Caused by: java.lang.Exception: Exception thrown in method3
    at UsingChainedExceptions.method3(UsingChainedExceptions.java:47)
    at UsingChainedExceptions.method2(UsingChainedExceptions.java:36)
    ... 2 more

```

**Fig. 11.6** | Chained exceptions. (Part 2 of 2.)

The program consists of four methods—`main` (lines 6–16), `method1` (lines 19–29), `method2` (lines 32–42) and `method3` (lines 45–48). Line 10 in method `main`'s try block calls `method1`. Line 23 in `method1`'s try block calls `method2`. Line 36 in `method2`'s try block calls `method3`. In `method3`, line 47 throws a new `Exception`. Because this statement is not in a try block, `method3` terminates, and the exception is returned to the calling method (`method2`) at line 36. This statement *is* in a try block; therefore, the try block terminates and the exception is caught at lines 38–41. Line 40 in the catch block throws a new exception. In this case, the `Exception` constructor with *two* arguments is called. The second argument represents the exception that was the original cause of the problem. In this program, that exception occurred at line 47. Because an exception is thrown from the catch block, `method2` terminates and returns the new exception to the calling method (`method1`) at line 23. Once again, this statement is in a try block, so the try block terminates and the exception is caught at lines 25–28. Line 27 in the catch block throws a new exception and uses the exception that was caught as the second argument to the `Exception` constructor. Because an exception is thrown from the catch block, `method1` terminates and returns the new exception to the calling method (`main`) at line 10. The try block in `main` terminates, and the exception is caught at lines 12–15. Line 14 prints a stack trace.

Notice in the program output that the first three lines show the most recent exception that was thrown (i.e., the one from `method1` at line 27). The next four lines indicate the exception that was thrown from `method2` at line 40. Finally, the last four lines represent the exception that was thrown from `method3` at line 47. Also notice that, as you read the output in reverse, it shows how many more chained exceptions remain.

## 11.9 Declaring New Exception Types

Most Java programmers use existing classes from the Java API, third-party vendors and freely available class libraries (usually downloadable from the Internet) to build Java applications. The methods of those classes typically are declared to throw appropriate exceptions when problems occur. You write code that processes these existing exceptions to make your programs more robust.

If you build classes that other programmers will use, you might find it useful to declare your own exception classes that are specific to the problems that can occur when another programmer uses your reusable classes.

### Software Engineering Observation 11.11

*If possible, indicate exceptions from your methods by using existing exception classes, rather than creating new ones. The Java API contains many exception classes that might be suitable for the type of problems your methods need to indicate.*

A new exception class must extend an existing exception class to ensure that the class can be used with the exception-handling mechanism. Like any other class, an exception class can contain fields and methods. A typical new exception class contains only four constructors: one that takes no arguments and passes a default error message `String` to the superclass constructor; one that receives a customized error message as a `String` and passes it to the superclass constructor; one that receives a customized error message as a `String` and a `Throwable` (for chaining exceptions) and passes both to the superclass constructor; and one that receives a `Throwable` (for chaining exceptions) and passes it to the superclass constructor.

### Good Programming Practice 11.3

*Associating each type of serious execution-time malfunction with an appropriately named Exception class improves program clarity.*

### Software Engineering Observation 11.12

*When defining your own exception type, study the existing exception classes in the Java API and try to extend a related exception class. For example, if you're creating a new class to represent when a method attempts a division by zero, you might extend class `ArithmeticException` because division by zero occurs during arithmetic. If the existing classes are not appropriate superclasses for your new exception class, decide whether your new class should be a checked or an unchecked exception class. The new exception class should be a checked exception (i.e., extend `Exception` but not `RuntimeException`) if clients should be required to handle the exception. The client application should be able to reasonably recover from such an exception. The new exception class should extend `RuntimeException` if the client code should be able to ignore the exception (i.e., the exception is an unchecked one).*

In Chapter 22, Custom Generic Data Structures, we provide an example of a custom exception class. We declare a reusable class called `List` that's capable of storing a list of references to objects. Some operations typically performed on a `List` are not allowed if the `List` is empty, such as removing an item from the front or back of the list. For this reason, some `List` methods throw exceptions of exception class `EmptyListException`.

### Good Programming Practice 11.4

*By convention, all exception-class names should end with the word `Exception`.*

## 11.10 Preconditions and Postconditions

Programmers spend significant amounts of time maintaining and debugging code. To facilitate these tasks and to improve the overall design, you can specify the expected states before and after a method's execution. These states are called preconditions and postconditions, respectively.

A **precondition** must be true when a method is *invoked*. Preconditions describe constraints on method parameters and any other expectations the method has about the current state of a program just before it begins executing. If the preconditions are not met, then the method's behavior is *undefined*—it may throw an exception, proceed with an illegal value or attempt to recover from the error. You should not expect consistent behavior if the preconditions are not satisfied.

A **postcondition** is true *after the method successfully returns*. Postconditions describe constraints on the return value and any other side effects the method may have. When defining a method, you should document all postconditions so that others know what to expect when they call your method, and you should make certain that your method honors all its postconditions if its preconditions are indeed met.

When their preconditions or postconditions are not met, methods typically throw exceptions. As an example, examine `String` method `charAt`, which has one `int` parameter—an index in the `String`. For a precondition, method `charAt` assumes that index is

greater than or equal to zero and less than the length of the `String`. If the precondition is met, the postcondition states that the method will return the character at the position in the `String` specified by the parameter `index`. Otherwise, the method throws an `IndexOutOfBoundsException`. We trust that method `charAt` satisfies its postcondition, provided that we meet the precondition. We need not be concerned with the details of how the method actually retrieves the character at the index.

Typically, a method's preconditions and postconditions are described as part of its specification. When designing your own methods, you should state the preconditions and postconditions in a comment before the method declaration.

## 11.11 Assertions

When implementing and debugging a class, it's sometimes useful to state conditions that should be true at a particular point in a method. These conditions, called **assertions**, help ensure a program's validity by catching potential bugs and identifying possible logic errors during development. Preconditions and postconditions are two types of assertions. Preconditions are assertions about its state when a method is invoked, and postconditions are assertions about a program's state after a method finishes.

While assertions can be stated as comments to guide you during program development, Java includes two versions of the **assert** statement for validating assertions programmatically. The `assert` statement evaluates a `boolean` expression and, if `false`, throws an **AssertionError** (a subclass of `Error`). The first form of the `assert` statement is

```
assert expression;
```

which throws an `AssertionError` if *expression* is `false`. The second form is

```
assert expression1 : expression2;
```

which evaluates *expression1* and throws an `AssertionError` with *expression2* as the error message if *expression1* is `false`.

You can use assertions to implement preconditions and postconditions programmatically or to verify any other intermediate states that help you ensure that your code is working correctly. Figure 11.7 demonstrates the `assert` statement. Line 11 prompts the user to enter a number between 0 and 10, then line 12 reads the number. Line 15 determines whether the user entered a number within the valid range. If the number is out of range, the `assert` statement reports an error; otherwise, the program proceeds normally.

---

```

1 // Fig. 11.7: AssertTest.java
2 // Checking with assert that a value is within range
3 import java.util.Scanner;
4
5 public class AssertTest
6 {
7     public static void main( String[] args )
8     {
9         Scanner input = new Scanner( System.in );
10

```

**Fig. 11.7** | Checking with `assert` that a value is within range. (Part 1 of 2.)

```

11     System.out.print( "Enter a number between 0 and 10: " );
12     int number = input.nextInt();
13
14     // assert that the value is >= 0 and <= 10
15     assert ( number >= 0 && number <= 10 ) : "bad number: " + number;
16
17     System.out.printf( "You entered %d\n", number );
18 } // end main
19 } // end class AssertTest

```

```

Enter a number between 0 and 10: 5
You entered 5

```

```

Enter a number between 0 and 10: 50
Exception in thread "main" java.lang.AssertionError: bad number: 50
    at AssertTest.main(AssertTest.java:15)

```

**Fig. 11.7** | Checking with assert that a value is within range. (Part 2 of 2.)

You use assertions primarily for debugging and identifying logic errors in an application. You must explicitly enable assertions when executing a program, because they reduce performance and are unnecessary for the program's user. To do so, use the `java` command's `-ea` command-line option, as in

```
java -ea AssertTest
```

Users should not encounter any `AssertionErrors` through normal execution of a properly written program. Such errors should only indicate bugs in the implementation. As a result, you should never catch an `AssertionError`. Rather, you should allow the program to terminate when the error occurs, so you can see the error message, then locate and fix the source of the problem. Since application users can choose not to enable assertions at runtime, you should not use `assert` to indicate runtime problems in production code—use the exception mechanism for this purpose.

## 11.12 (New in Java SE 7) Multi-catch: Handling Multiple Exceptions in One catch

It's relatively common for a `try` block to be followed by several `catch` blocks to handle various types of exceptions. If the bodies of several `catch` blocks are identical, you can use the new Java SE 7 **multi-catch** feature to catch those exception types in a single `catch` handler and perform the same task. The syntax for a multi-catch is:

```
catch ( Type1 | Type2 | Type3 e )
```

Each exception type is separated from the next with a vertical bar (`|`). The preceding line of code indicates that one of the specified types (or any subclasses of those types) can be caught in the exception handler. Any number of `Throwable` types can be specified in a multi-catch.

## 11.13 (New in Java SE 7) try-with-Resources: Automatic Resource Deallocation

Typically resource-release code should be placed in a `finally` block to ensure that a resource is released, regardless of whether there were exceptions when the resource was used in the corresponding `try` block. An alternative notation—the **try-with-resources** statement (which is new in Java SE 7)—simplifies writing code in which you obtain one or more resources, use them in a `try` block and release them in a corresponding `finally` block. For example, a file-processing application (Chapter 17) could process a file with a try-with-resources statement to ensure that the file is closed properly when it's no longer needed. Each resource must be an object of a class that implements the **AutoCloseable** interface—such a class has a `close` method. The general form of a try-with-resources statement is

```
try ( ClassName theObject = new ClassName() )
{
    // use theObject here
}
catch ( Exception e )
{
    // catch exceptions that occur while using the resource
}
```

where *ClassName* is a class that implements the `AutoCloseable` interface. This code creates an object of type *ClassName* and uses it in the `try` block, then calls its `close` method to release any resources used by the object. The try-with-resources statement *implicitly* calls the `theObject`'s `close` method *at the end of the try block*. You can allocate multiple resources in the parentheses following `try` by separating them with a semicolon (;).

## 11.14 Wrap-Up

In this chapter, you learned how to use exception handling to deal with errors. You learned that exception handling enables you to remove error-handling code from the “main line” of the program’s execution. We showed how to use `try` blocks to enclose code that may throw an exception, and how to use `catch` blocks to deal with exceptions that may arise. You learned about the termination model of exception handling, which dictates that after an exception is handled, program control does not return to the throw point. We discussed checked vs. unchecked exceptions, and how to specify with the `throws` clause the exceptions that a method might throw. You learned how to use the `finally` block to release resources whether or not an exception occurs. You also learned how to throw and rethrow exceptions. We showed how to obtain information about an exception using methods `printStackTrace`, `getStackTrace` and `getMessage`. Next, we presented chained exceptions, which allow you to wrap original exception information with new exception information. Then, we showed how to create your own exception classes. We introduced preconditions and postconditions to help programmers using your methods understand conditions that must be true when the method is called and when it returns, respectively. When preconditions and postconditions are not met, methods typically throw exceptions. We discussed the `assert` statement and how it can be used to help you debug your programs. In particular, `assert` can be used to ensure that preconditions and postconditions

are met. Finally, we introduced Java SE 7's new exception-handling features, including multi-catch for processing several types of exceptions in the same catch handler and the try-with-resources statement for automatically deallocating a resource after it's used in the try block. In the next chapter, we begin our two-chapter, optional case study on object-oriented design with the UML.

## Summary

### *Section 11.1 Introduction*

- An exception is an indication of a problem that occurs during a program's execution.
- Exception handling enables programmers to create applications that can resolve exceptions.

### *Section 11.2 Example: Divide by Zero without Exception Handling*

- Exceptions are thrown (p. 440) when a method detects a problem and is unable to handle it.
- An exception's stack trace (p. 441) includes the name of the exception in a message that indicates the problem that occurred and the complete method-call stack at the time the exception occurred.
- The point in the program at which an exception occurs is called the throw point (p. 441).

### *Section 11.3 Example: Handling ArithmeticExceptions and InputMismatchExceptions*

- A try block (p. 444) encloses code that might throw an exception and code that should not execute if that exception occurs.
- Exceptions may surface through explicitly mentioned code in a try block, through calls to other methods or even through deeply nested method calls initiated by code in the try block.
- A catch block (p. 444) begins with keyword catch and an exception parameter followed by a block of code that handles the exception. This code executes when the try block detects the exception.
- An uncaught exception is an exception that occurs for which there are no matching catch blocks.
- An uncaught exception (p. 445) will cause a program to terminate early if that program contains only one thread. Otherwise, only the thread where the exception occurred will terminate. The rest of the program will run but possibly with adverse results.
- At least one catch block or a finally block (p. 444) must immediately follow the try block.
- A catch block specifies in parentheses an exception parameter identifying the exception type to handle. The parameter's name enables the catch block to interact with a caught exception object.
- If an exception occurs in a try block, the try block terminates immediately and program control transfers to the first catch block with a parameter type that matches the thrown exception's type.
- After an exception is handled, program control does not return to the throw point, because the try block has expired. This is known as the termination model of exception handling (p. 445).
- If there are multiple matching catch blocks when an exception occurs, only the first is executed.
- A throws clause (p. 446) specifies a comma-separated list of exceptions that the method might throw, and appears after the method's parameter list and before the method body.

### *Section 11.4 When to Use Exception Handling*

- Exception handling processes synchronous errors (p. 447), which occur when a statement executes.
- Exception handling is not designed to process problems associated with asynchronous events (p. 447), which occur in parallel with, and independent of, the program's flow of control.

### *Section 11.5 Java Exception Hierarchy*

- All Java exception classes inherit directly or indirectly from class `Exception`.
- Programmers can extend the Java exception hierarchy with their own exception classes.
- Class `Throwable` is the superclass of class `Exception` and is therefore also the superclass of all exceptions. Only `Throwable` objects can be used with the exception-handling mechanism.
- Class `Throwable` (p. 447) has two subclasses: `Exception` and `Error`.
- Class `Exception` and its subclasses represent problems that could occur in a Java program and be caught by the application.
- Class `Error` and its subclasses represent problems that could happen in the Java runtime system. Errors happen infrequently and typically should not be caught by an application.
- Java distinguishes between two categories of exceptions (p. 448): checked and unchecked.
- The Java compiler does not check to determine if an unchecked exception is caught or declared. Unchecked exceptions typically can be prevented by proper coding.
- Subclasses of `RuntimeException` represent unchecked exceptions. All exception types that inherit from class `Exception` but not from `RuntimeException` (p. 448) are checked.
- If a catch block is written to catch exception objects of a superclass type, it can also catch all objects of that class's subclasses. This allows for polymorphic processing of related exceptions.

### *Section 11.6 finally block*

- Programs that obtain certain types of resources must return them to the system to avoid so-called resource leaks (p. 450). Resource-release code typically is placed in a `finally` block (p. 450).
- The `finally` block is optional. If it's present, it's placed after the last catch block.
- The `finally` block will execute whether or not an exception is thrown in the corresponding try block or any of its corresponding catch blocks.
- If an exception cannot be caught by one of that try block's associated catch handlers, control proceeds to the `finally` block. Then the exception is passed to the next outer try block.
- If a catch block throws an exception, the `finally` block still executes. Then the exception is passed to the next outer try block.
- A `throw` statement (p. 453) can throw any `Throwable` object.
- Exceptions are rethrown (p. 453) when a catch block, upon receiving an exception, decides either that it cannot process that exception or that it can only partially process it. Rethrowing an exception defers the exception handling (or perhaps a portion of it) to another catch block.
- When a rethrow occurs, the next enclosing try block detects the rethrown exception, and that try block's catch blocks attempt to handle it.

### *Section 11.7 Stack Unwinding and Obtaining Information from an Exception Object*

- When an exception is thrown but not caught in a particular scope, the method-call stack is unwound, and an attempt is made to catch the exception in the next outer try statement.
- Class `Throwable` offers a `printStackTrace` method that prints the method-call stack. Often, this is helpful in testing and debugging.
- Class `Throwable` also provides a `getStackTrace` method that obtains the same stack-trace information that's printed by `printStackTrace` (p. 456).
- Class `Throwable`'s `getMessage` method (p. 456) returns the descriptive string stored in an exception.
- Method `getStackTrace` (p. 456) obtains the stack-trace information as an array of `StackTraceElement` objects. Each `StackTraceElement` represents one method call on the method-call stack.

- StackTraceElement methods (p. 457) getClassName, getFileName, getLineNumber and getMethodName get the class name, file name, line number and method name, respectively.

### Section 11.8 Chained Exceptions

- Chained exceptions (p. 457) enable an exception object to maintain the complete stack-trace information, including information about previous exceptions that caused the current exception.

### Section 11.9 Declaring New Exception Types

- A new exception class must extend an existing exception class to ensure that the class can be used with the exception-handling mechanism.

### Section 11.10 Preconditions and Postconditions

- A method's precondition (p. 460) must be true when the method is invoked.
- A method's postcondition (p. 460) is true after the method successfully returns.
- When designing your own methods, you should state the preconditions and postconditions in a comment before the method declaration.

### Section 11.11 Assertions

- Assertions (p. 461) help catch potential bugs and identify possible logic errors.
- The assert statement (p. 461) allows for validating assertions programmatically.
- To enable assertions at runtime, use the -ea switch when running the java command.

### Section 11.12 Multi-catch: Handling Multiple Exceptions in One catch

- Java SE 7's multi-catch (p. 462) enables you to catch multiple exception types in a single catch handler and perform the same task for each type of exception. The syntax for a multi-catch is:  

```
catch ( Type1 | Type2 | Type3 e )
```
- Each exception type is separated from the next with a vertical bar (|).

### Section 11.13 try-with-Resources: Automatic Resource Deallocation

- The try-with-resources statement (p. 463) simplifies writing code in which you obtain a resource, use it in a try block and release the resource in a corresponding finally block. Instead, you allocate the resource in the parentheses following the try keyword and use the resource in the try block; then the statement implicitly calls the resource's close method at the end of the try block.
- Each resource must be an object of a class that implements the AutoCloseable interface (p. 463)—such a class has a close method.
- You can allocate multiple resources in the parentheses following try by separating them with a semicolon (;).

## Self-Review Exercises

- 11.1 List five common examples of exceptions.
- 11.2 Give several reasons why exception-handling techniques should not be used for conventional program control.
- 11.3 Why are exceptions particularly appropriate for dealing with errors produced by methods of classes in the Java API?
- 11.4 What is a “resource leak”?
- 11.5 If no exceptions are thrown in a try block, where does control proceed to when the try block completes execution?

- 11.6 Give a key advantage of using `catch( Exception exceptionName )`.
- 11.7 Should a conventional application catch `Error` objects? Explain.
- 11.8 What happens if no catch handler matches the type of a thrown object?
- 11.9 What happens if several catch blocks match the type of the thrown object?
- 11.10 Why would a programmer specify a superclass type as the type in a catch block?
- 11.11 What is the key reason for using `finally` blocks?
- 11.12 What happens when a catch block throws an `Exception`?
- 11.13 What does the statement `throw exceptionReference` do in a catch block?
- 11.14 What happens to a local reference in a `try` block when that block throws an `Exception`?

## Answers to Self-Review Exercises

11.1 Memory exhaustion, array index out of bounds, arithmetic overflow, division by zero, invalid method parameters.

11.2 (a) Exception handling is designed to handle infrequently occurring situations that often result in program termination, not situations that arise all the time. (b) Flow of control with conventional control structures is generally clearer and more efficient than with exceptions. (c) The additional exceptions can get in the way of genuine error-type exceptions. It becomes more difficult for you to keep track of the larger number of exception cases.

11.3 It's unlikely that methods of classes in the Java API could perform error processing that would meet the unique needs of all users.

11.4 A "resource leak" occurs when an executing program does not properly release a resource when it's no longer needed.

11.5 The catch blocks for that `try` statement are skipped, and the program resumes execution after the last catch block. If there's a `finally` block, it's executed first; then the program resumes execution after the `finally` block.

11.6 The form `catch( Exception exceptionName )` catches any type of exception thrown in a `try` block. An advantage is that no thrown `Exception` can slip by without being caught. You can then decide to handle the exception or possibly rethrow it.

11.7 Errors are usually serious problems with the underlying Java system; most programs will not want to catch `Errors` because they will not be able to recover from them.

11.8 This causes the search for a match to continue in the next enclosing `try` statement. If there's a `finally` block, it will be executed before the exception goes to the next enclosing `try` statement. If there are no enclosing `try` statements for which there are matching catch blocks and the exceptions are declared (or unchecked), a stack trace is printed and the current thread terminates early. If the exceptions are checked, but not caught or declared, compilation errors occur.

11.9 The first matching catch block after the `try` block is executed.

11.10 This enables a program to catch related types of exceptions and process them in a uniform manner. However, it's often useful to process the subclass types individually for more precise exception handling.

11.11 The `finally` block is the preferred means for releasing resources to prevent resource leaks.

11.12 First, control passes to the `finally` block if there is one. Then the exception will be processed by a catch block (if one exists) associated with an enclosing `try` block (if one exists).

11.13 It rethrows the exception for processing by an exception handler of an enclosing `try` statement, after the `finally` block of the current `try` statement executes.

**11.14** The reference goes out of scope. If the referenced object becomes unreachable, the object can be garbage collected.

## Exercises

**11.15** (*Exceptional Conditions*) List the various exceptional conditions that have occurred in programs throughout this text so far. List as many additional exceptional conditions as you can. For each of these, describe briefly how a program typically would handle the exception by using the exception-handling techniques discussed in this chapter. Typical exceptions include division by zero and array index out of bounds.

**11.16** (*Exceptions and Constructor Failure*) Until this chapter, we've found dealing with errors detected by constructors to be a bit awkward. Explain why exception handling is an effective means for dealing with constructor failure.

**11.17** (*Catching Exceptions with Superclasses*) Use inheritance to create an exception superclass (called `ExceptionA`) and exception subclasses `ExceptionB` and `ExceptionC`, where `ExceptionB` inherits from `ExceptionA` and `ExceptionC` inherits from `ExceptionB`. Write a program to demonstrate that the catch block for type `ExceptionA` catches exceptions of types `ExceptionB` and `ExceptionC`.

**11.18** (*Catching Exceptions Using Class Exception*) Write a program that demonstrates how various exceptions are caught with

```
catch ( Exception exception )
```

This time, define classes `ExceptionA` (which inherits from class `Exception`) and `ExceptionB` (which inherits from class `ExceptionA`). In your program, create try blocks that throw exceptions of types `ExceptionA`, `ExceptionB`, `NullPointerException` and `IOException`. All exceptions should be caught with catch blocks specifying type `Exception`.

**11.19** (*Order of catch Blocks*) Write a program that shows that the order of catch blocks is important. If you try to catch a superclass exception type before a subclass type, the compiler should generate errors.

**11.20** (*Constructor Failure*) Write a program that shows a constructor passing information about constructor failure to an exception handler. Define class `SomeClass`, which throws an `Exception` in the constructor. Your program should try to create an object of type `SomeClass` and catch the exception that's thrown from the constructor.

**11.21** (*Rethrowing Exceptions*) Write a program that illustrates rethrowing an exception. Define methods `someMethod` and `someMethod2`. Method `someMethod2` should initially throw an exception. Method `someMethod` should call `someMethod2`, catch the exception and rethrow it. Call `someMethod` from method `main`, and catch the rethrown exception. Print the stack trace of this exception.

**11.22** (*Catching Exceptions Using Outer Scopes*) Write a program showing that a method with its own try block does not have to catch every possible error generated within the try. Some exceptions can slip through to, and be handled in, other scopes.

## Objectives

In this chapter you'll learn:

- A simple object-oriented design methodology.
- What a requirements document is.
- To identify classes and class attributes from a requirements document.
- To identify objects' states, activities and operations from a requirements document.
- To determine the collaborations among objects in a system.
- To work with the UML's use case, class, state, activity, communication and sequence diagrams to graphically model an object-oriented system.

|                                                                |                                                        |

*Answers to Self-Review Exercises*

## 12.1 Case Study Introduction

Now we begin the *optional* portion of our object-oriented design and implementation case study. In this chapter and Chapter 13, you'll design and implement an object-oriented automated teller machine (ATM) software system. The case study provides you with a concise, carefully paced, complete design and implementation experience. In Sections 12.2–12.7 and 13.2–13.3, you'll perform the steps of an object-oriented design (OOD) process using the UML while relating these steps to the object-oriented concepts discussed in Chapters 2–10. In this chapter, you'll work with six popular types of UML diagrams to graphically represent the design. In Chapter 13, you'll tune the design with inheritance, then fully implement the ATM in a 673-line Java application (Section 13.4).

This is not an exercise; rather, it's an end-to-end learning experience that concludes with a detailed walkthrough of the complete Java code that implements our design. It will begin to acquaint you with the kinds of substantial problems encountered in industry.

These chapters can be studied as a continuous unit after you've completed the introduction to object-oriented programming in Chapters 8–11. Or, you can pace the sections one at a time after Chapters 2–8 and 10. Each section of the case study begins with a note telling you the chapter after which it can be covered.

## 12.2 Examining the Requirements Document

[*Note:* This section can be taught after Chapter 2.]

We begin our design process by presenting a **requirements document** that specifies the purpose of the ATM system and *what* it must do. Throughout the case study, we refer often to this requirements document.

### *Requirements Document*

A local bank intends to install a new automated teller machine (ATM) to allow users (i.e., bank customers) to perform basic financial transactions (Fig. 12.1). Each user can have only one account at the bank. ATM users should be able to view their account balance, withdraw cash (i.e., take money out of an account) and deposit funds (i.e., place money into an account). The user interface of the automated teller machine contains:

- a screen that displays messages to the user
- a keypad that receives numeric input from the user
- a cash dispenser that dispenses cash to the user and
- a deposit slot that receives deposit envelopes from the user.

The cash dispenser begins each day loaded with 500 \$20 bills. [Note: Owing to the limited scope of this case study, certain elements of the ATM described here do not accurately mimic those of a real ATM. For example, a real ATM typically contains a device that reads a user's account number from an ATM card, whereas this ATM asks the user to type the account number on the keypad. A real ATM also usually prints a receipt at the end of a session, but all output from this ATM appears on the screen.]

**Fig. 12.1** | Automated teller machine user interface.

The bank wants you to develop software to perform the financial transactions initiated by bank customers through the ATM. The bank will integrate the software with the ATM's hardware at a later time. The software should encapsulate the functionality of the hardware devices (e.g., cash dispenser, deposit slot) within software components, but it need not concern itself with how these devices perform their duties. The ATM hardware has not been developed yet, so instead of writing your software to run on the ATM, you should develop a first version to run on a personal computer. This version should use the computer's monitor to simulate the ATM's screen, and the computer's keyboard to simulate the ATM's keypad.

An ATM session consists of authenticating a user (i.e., proving the user's identity) based on an account number and personal identification number (PIN), followed by creating and executing financial transactions. To authenticate a user and perform transactions, the ATM must interact with the bank's account information database (i.e., an organized collection of data stored on a computer; we study database access in Chapter 28). For each bank account, the database stores an account number, a PIN and a balance indicating the amount of money in the account. [Note: We assume that the bank plans to build only one ATM, so we need not worry about multiple ATMs accessing this database at the same time. Furthermore, we assume that the bank does not make any changes to the information in the database while a user is accessing the ATM. Also, any

business system like an ATM faces complex and challenging security issues that are beyond the scope of a first or second programming course. We make the simplifying assumption, however, that the bank trusts the ATM to access and manipulate the information in the database without significant security measures.]

Upon first approaching the ATM (assuming no one is currently using it), the user should experience the following sequence of events (shown in Fig. 12.1):

1. The screen displays Welcome! and prompts the user to enter an account number.
2. The user enters a five-digit account number using the keypad.
3. The screen prompts the user to enter the PIN (personal identification number) associated with the specified account number.
4. The user enters a five-digit PIN using the keypad.<sup>1</sup>
5. If the user enters a valid account number and the correct PIN for that account, the screen displays the main menu (Fig. 12.2). If the user enters an invalid account number or an incorrect PIN, the screen displays an appropriate message, then the ATM returns to *Step 1* to restart the authentication process.

**Fig. 12.2** | ATM main menu.

After the ATM authenticates the user, the main menu (Fig. 12.2) should contain a numbered option for each of the three types of transactions: balance inquiry (option 1),

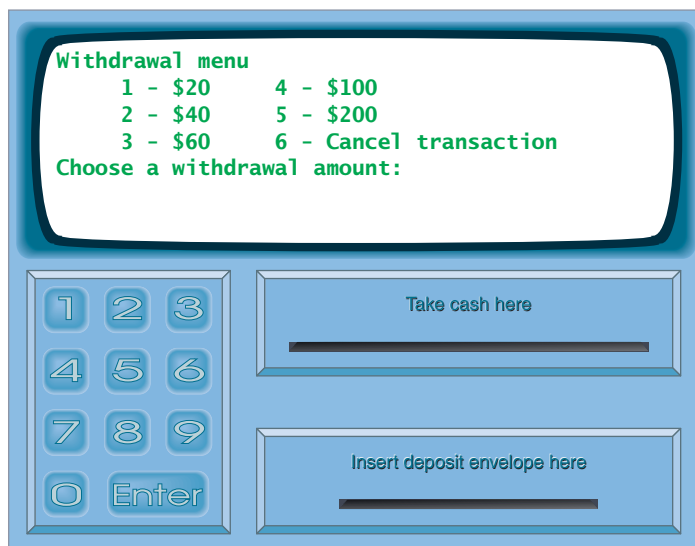

1. In this simple, command-line, text-based ATM, as you type the PIN, it appears on the screen. This is an obvious security breach—you would not want someone looking over your shoulder at an ATM and seeing your PIN displayed on the screen. In Chapter 14, we introduce the `JPasswordField` GUI component, which displays asterisks as the user types—making it more appropriate for entering PIN numbers and passwords. Exercise 14.18 asks you to build a GUI-based version of the ATM and to use a `JPasswordField` to obtain the user's PIN.

withdrawal (option 2) and deposit (option 3). It also should contain an option to allow the user to exit the system (option 4). The user then chooses either to perform a transaction (by entering 1, 2 or 3) or to exit the system (by entering 4).

If the user enters 1 to make a balance inquiry, the screen displays the user's account balance. To do so, the ATM must retrieve the balance from the bank's database. The following steps describe what occurs when the user enters 2 to make a withdrawal:

1. The screen displays a menu (Fig. 12.3) containing standard withdrawal amounts: \$20 (option 1), \$40 (option 2), \$60 (option 3), \$100 (option 4) and \$200 (option 5). The menu also contains an option to allow the user to cancel the transaction (option 6).

**Fig. 12.3** | ATM withdrawal menu.

2. The user enters a menu selection using the keypad.
3. If the withdrawal amount chosen is greater than the user's account balance, the screen displays a message stating this and telling the user to choose a smaller amount. The ATM then returns to *Step 1*. If the withdrawal amount chosen is less than or equal to the user's account balance (i.e., an acceptable amount), the ATM proceeds to *Step 4*. If the user chooses to cancel the transaction (option 6), the ATM displays the main menu and waits for user input.
4. If the cash dispenser contains enough cash, the ATM proceeds to *Step 5*. Otherwise, the screen displays a message indicating the problem and telling the user to choose a smaller withdrawal amount. The ATM then returns to *Step 1*.
5. The ATM debits the withdrawal amount from the user's account in the bank's database (i.e., subtracts the withdrawal amount from the user's account balance).
6. The cash dispenser dispenses the desired amount of money to the user.

7. The screen displays a message reminding the user to take the money.

The following steps describe the actions that occur when the user enters 3 (when viewing the main menu of Fig. 12.2) to make a deposit:

1. The screen prompts the user to enter a deposit amount or type 0 (zero) to cancel.
2. The user enters a deposit amount or 0 using the keypad. [*Note:* The keypad does not contain a decimal point or a dollar sign, so the user cannot type a real dollar amount (e.g., \$27.25). Instead, the user must enter a deposit amount as a number of cents (e.g., 2725). The ATM then divides this number by 100 to obtain a number representing a dollar amount (e.g.,  $2725 \div 100 = 27.25$ ).]
3. If the user specifies a deposit amount, the ATM proceeds to *Step 4*. If the user chooses to cancel the transaction (by entering 0), the ATM displays the main menu and waits for user input.
4. The screen displays a message telling the user to insert a deposit envelope.
5. If the deposit slot receives a deposit envelope within two minutes, the ATM credits the deposit amount to the user's account in the bank's database (i.e., adds the deposit amount to the user's account balance). [*Note:* This money is *not* immediately available for withdrawal. The bank first must physically verify the amount of cash in the deposit envelope, and any checks in the envelope must clear (i.e., money must be transferred from the check writer's account to the check recipient's account). When either of these events occurs, the bank appropriately updates the user's balance stored in its database. This occurs independently of the ATM system.] If the deposit slot does not receive a deposit envelope within this time period, the screen displays a message that the system has canceled the transaction due to inactivity. The ATM then displays the main menu and waits for user input.

After the system successfully executes a transaction, it should return to the main menu so that the user can perform additional transactions. If the user exits the system, the screen should display a thank you message, then display the welcome message for the next user.

### *Analyzing the ATM System*

The preceding statement is a simplified example of a requirements document. Typically, such a document is the result of a detailed process of **requirements gathering**, which might include interviews with possible users of the system and specialists in fields related to the system. For example, a systems analyst who is hired to prepare a requirements document for banking software (e.g., the ATM system described here) might interview banking experts to gain a better understanding of what the software must do. The analyst would use the information gained to compile a list of **system requirements** to guide systems designers as they design the system.

The process of requirements gathering is a key task of the first stage of the software life cycle. The **software life cycle** specifies the stages through which software goes from the time it's first conceived to the time it's retired from use. These stages typically include: analysis, design, implementation, testing and debugging, deployment, maintenance and retirement. Several software life-cycle models exist, each with its own preferences and specifications for when and how often software engineers should perform each of these stages.

**Waterfall models** perform each stage once in succession, whereas **iterative models** may *repeat* one or more stages several times throughout a product’s life cycle.

The analysis stage focuses on defining the problem to be solved. When designing any system, one must *solve the problem right*, but of equal importance, one must *solve the right problem*. Systems analysts collect the requirements that indicate the specific problem to solve. Our requirements document describes the requirements of our ATM system in sufficient detail that you need not go through an extensive analysis stage—it’s been done for you.

To capture what a proposed system should do, developers often employ a technique known as **use case modeling**. This process identifies the **use cases** of the system, each representing a different capability that the system provides to its clients. For example, ATMs typically have several use cases, such as “View Account Balance,” “Withdraw Cash,” “Deposit Funds,” “Transfer Funds Between Accounts” and “Buy Postage Stamps.” The simplified ATM system we build in this case study allows only the first three.

Each use case describes a typical scenario for which the user uses the system. You’ve already read descriptions of the ATM system’s use cases in the requirements document; the lists of steps required to perform each transaction type (i.e., balance inquiry, withdrawal and deposit) actually described the three use cases of our ATM—“View Account Balance,” “Withdraw Cash” and “Deposit Funds,” respectively.

### Use Case Diagrams

We now introduce the first of several UML diagrams in the case study. We create a **use case diagram** to model the interactions between a system’s clients (in this case study, bank customers) and its use cases. The goal is to show the kinds of interactions users have with a system without providing the details—these are provided in other UML diagrams (which we present throughout this case study). Use case diagrams are often accompanied by informal text that gives more detail—like the text that appears in the requirements document. Use case diagrams are produced during the analysis stage of the software life cycle. In larger systems, use case diagrams are indispensable tools that help system designers remain focused on satisfying the users’ needs.

Figure 12.4 shows the use case diagram for our ATM system. The stick figure represents an **actor**, which defines the roles that an external entity—such as a person or another system—plays when interacting with the system. For our automated teller machine, the actor is a User who can view an account balance, withdraw cash and deposit funds from

**Fig. 12.4** | Use case diagram for the ATM system from the User’s perspective.

the ATM. The User is not an actual person, but instead comprises the roles that a real person—when playing the part of a User—can play while interacting with the ATM. A use case diagram can include multiple actors. For example, the use case diagram for a real bank’s ATM system might also include an actor named Administrator who refills the cash dispenser each day.

Our requirements document supplies the actors—“ATM users should be able to view their account balance, withdraw cash and deposit funds.” Therefore, the actor in each of the three use cases is the user who interacts with the ATM. An external entity—a real person—plays the part of the user to perform financial transactions. Figure 12.4 shows one actor, whose name, User, appears below the actor in the diagram. The UML models each use case as an oval connected to an actor with a solid line.

Software engineers (more precisely, systems designers) must analyze the requirements document or a set of use cases and design the system before programmers implement it in a particular programming language. During the analysis stage, systems designers focus on understanding the requirements document to produce a high-level specification that describes *what* the system is supposed to do. The output of the design stage—a **design specification**—should specify clearly *how* the system should be constructed to satisfy these requirements. In the next several sections, we perform the steps of a simple object-oriented design (OOD) process on the ATM system to produce a design specification containing a collection of UML diagrams and supporting text.

The UML is designed for use with any OOD process. Many such processes exist, the best known of which is the Rational Unified Process™ (RUP) developed by Rational Software Corporation, now part of IBM. RUP is a rich process intended for designing “industrial strength” applications. For this case study, we present our own simplified design process, designed for students in first and second programming courses.

### *Designing the ATM System*

We now begin the design stage of our ATM system. A **system** is a set of components that interact to solve a problem. For example, to perform the ATM system’s designated tasks, our ATM system has a user interface (Fig. 12.1), and contains software that executes financial transactions and interacts with a database of bank account information. **System structure** describes the system’s objects and their interrelationships. **System behavior** describes how the system changes as its objects interact with one another.

Every system has both structure and behavior—designers must specify both. There are several types of system structures and behaviors. For example, the interactions among objects in the system differ from those between the user and the system, yet both constitute a portion of the system behavior.

The UML 2 standard specifies 13 diagram types for documenting the system models. Each models a distinct characteristic of a system’s structure or behavior—six diagrams relate to system structure, the remaining seven to system behavior. We list here only the six diagram types used in our case study—one models system structure; the other five model system behavior. We provide an overview of the remaining seven UML diagram types in Appendix P, UML 2: Additional Diagram Types.

1. **Use case diagrams**, such as the one in Fig. 12.4, model the interactions between a system and its external entities (actors) in terms of use cases (system capabilities, such as “View Account Balance,” “Withdraw Cash” and “Deposit Funds”).

2. **Class diagrams**, which you'll study in Section 12.3, model the classes, or “building blocks,” used in a system. Each noun or “thing” described in the requirements document is a candidate to be a class in the system (e.g., Account, Keypad). Class diagrams help us specify the *structural relationships* between parts of the system. For example, the ATM system class diagram will specify that the ATM is physically *composed of* a screen, a keypad, a cash dispenser and a deposit slot.
3. **State machine diagrams**, which you'll study in Section 12.5, model the ways in which an object changes state. An object's **state** is indicated by the values of all its attributes at a given time. When an object changes state, it may behave differently in the system. For example, after validating a user's PIN, the ATM transitions from the “user not authenticated” state to the “user authenticated” state, at which point it allows the user to perform financial transactions (e.g., view account balance, withdraw cash, deposit funds).
4. **Activity diagrams**, which you'll also study in Section 12.5, model an object's **activity**—is workflow (sequence of events) during program execution. An activity diagram models the *actions* the object performs and specifies the *order* in which it performs them. For example, an activity diagram shows that the ATM must obtain the balance of the user's account (from the bank's account information database) *before* the screen can display the balance to the user.
5. **Communication diagrams** (called **collaboration diagrams** in earlier versions of the UML) model the interactions among objects in a system, with an emphasis on *what* interactions occur. You'll learn in Section 12.7 that these diagrams show which objects must interact to perform an ATM transaction. For example, the ATM must communicate with the bank's account information database to retrieve an account balance.
6. **Sequence diagrams** also model the interactions among the objects in a system, but unlike communication diagrams, they emphasize *when* interactions occur. You'll learn in Section 12.7 that these diagrams help show the order in which interactions occur in executing a financial transaction. For example, the screen prompts the user to enter a withdrawal amount before cash is dispensed.

In Section 12.3, we continue designing our ATM system by identifying the classes from the requirements document. We accomplish this by extracting key *nouns and noun phrases* from the requirements document. Using these classes, we develop our first draft of the class diagram that models the structure of our ATM system.

### Web Resource

We've created an extensive UML Resource Center that contains many links to additional information, including introductions, tutorials, blogs, books, certification, conferences, developer tools, documentation, e-books, FAQs, forums, groups, UML in Java, podcasts, security, tools, downloads, training courses, videos and more. Browse our UML Resource Center at [www.deitel.com/UML/](http://www.deitel.com/UML/).

## Self-Review Exercises for Section 12.2

**12.1** Suppose we enabled a user of our ATM system to transfer money between two bank accounts. Modify the use case diagram of Fig. 12.4 to reflect this change.

**12.2** \_\_\_\_\_ model the interactions among objects in a system with an emphasis on *when* these interactions occur.

- Class diagrams
- Sequence diagrams
- Communication diagrams
- Activity diagrams

**12.3** Which of the following choices lists stages of a typical software life cycle in sequential order?

- design, analysis, implementation, testing
- design, analysis, testing, implementation
- analysis, design, testing, implementation
- analysis, design, implementation, testing

## 12.3 Identifying the Classes in a Requirements Document

[*Note: This section can be taught after Chapter 3.*]

Now we begin designing the ATM system. In this section, we identify the classes that are needed to build the system by analyzing the *nouns* and *noun phrases* that appear in the requirements document. We introduce UML class diagrams to model these classes. This is an important first step in defining the system’s structure.

### *Identifying the Classes in a System*

We begin our OOD process by identifying the classes required to build the ATM system. We’ll eventually describe these classes using UML class diagrams and implement these classes in Java. First, we review the requirements document of Section 12.2 and identify key nouns and noun phrases to help us identify classes that comprise the ATM system. We may decide that some of these are actually attributes of other classes in the system. We may also conclude that some of the nouns do not correspond to parts of the system and thus should not be modeled at all. Additional classes may become apparent to us as we proceed through the design process.

Figure 12.5 lists the nouns and noun phrases found in the requirements document. We list them from left to right in the order in which we first encounter them. We list only the singular form of each.

| Nouns and noun phrases in the ATM requirements document |                  |                |                  |
|---------------------------------------------------------|------------------|----------------|------------------|
| bank                                                    | money / funds    | account number | ATM              |
| screen                                                  | PIN              | user           | keypad           |
| bank database                                           | customer         | cash dispenser | balance inquiry  |
| transaction                                             | \$20 bill / cash | withdrawal     | account          |
| deposit slot                                            | deposit          | balance        | deposit envelope |

**Fig. 12.5** | Nouns and noun phrases in the ATM requirements document.

We create classes only for the nouns and noun phrases that have significance in the ATM system. We don’t model “bank” as a class, because the bank is not a part of the ATM system—the bank simply wants us to build the ATM. “Customer” and “user” also repre-

sent outside entities—they're important because they *interact* with our ATM system, but we do not need to model them as classes in the ATM software. Recall that we modeled an ATM user (i.e., a bank customer) as the actor in the use case diagram of Fig. 12.4.

We do not model “\$20 bill” or “deposit envelope” as classes. These are physical objects in the real world, but they're not part of what is being automated. We can adequately represent the presence of bills in the system using an attribute of the class that models the cash dispenser. (We assign attributes to the ATM system's classes in Section 12.4.) For example, the cash dispenser maintains a count of the number of bills it contains. The requirements document does not say anything about what the system should do with deposit envelopes after it receives them. We can assume that simply acknowledging the receipt of an envelope—an operation performed by the class that models the deposit slot—is sufficient to represent the presence of an envelope in the system. We assign operations to the ATM system's classes in Section 12.6.

In our simplified ATM system, representing various amounts of “money,” including an account's “balance,” as attributes of classes seems most appropriate. Likewise, the nouns “account number” and “PIN” represent significant pieces of information in the ATM system. They're important attributes of a bank account. They do not, however, exhibit behaviors. Thus, we can most appropriately model them as attributes of an account class.

Though the requirements document frequently describes a “transaction” in a general sense, we do not model the broad notion of a financial transaction at this time. Instead, we model the three types of transactions (i.e., “balance inquiry,” “withdrawal” and “deposit”) as individual classes. These classes possess specific attributes needed for executing the transactions they represent. For example, a withdrawal needs to know the amount of the withdrawal. A balance inquiry, however, does not require any additional data other than the account number. Furthermore, the three transaction classes exhibit unique behaviors. A withdrawal includes dispensing cash to the user, whereas a deposit involves receiving deposit envelopes from the user. In Section 13.3, we “factor out” common features of all transactions into a general “transaction” class using the object-oriented concept of inheritance.

We determine the classes for our system based on the remaining nouns and noun phrases from Fig. 12.5. Each of these refers to one or more of the following:

- ATM
- screen
- keypad
- cash dispenser
- deposit slot
- account
- bank database
- balance inquiry
- withdrawal
- deposit

The elements of this list are likely to be classes that we'll need to implement our system.

We can now model the classes in our system based on the list we've created. We capitalize class names in the design process—a UML convention—as we'll do when we write

the actual Java code that implements our design. If the name of a class contains more than one word, we run the words together and capitalize each word (e.g., `MultipleWordName`). Using this convention, we create classes `ATM`, `Screen`, `Keypad`, `CashDispenser`, `DepositSlot`, `Account`, `BankDatabase`, `BalanceInquiry`, `Withdrawal` and `Deposit`. We construct our system using these classes as building blocks. Before we begin building the system, however, we must gain a better understanding of how the classes relate to one another.

### Modeling Classes

The UML enables us to model, via **class diagrams**, the classes in the ATM system and their interrelationships. Figure 12.6 represents class `ATM`. Each class is modeled as a rectangle with three compartments. The top one contains the name of the class centered horizontally in boldface. The middle compartment contains the class's attributes. (We discuss attributes in Sections 12.4–12.5.) The bottom compartment contains the class's operations (discussed in Section 12.6). In Fig. 12.6, the middle and bottom compartments are empty because we've not yet determined this class's attributes and operations.

**Fig. 12.6** | Representing a class in the UML using a class diagram.

Class diagrams also show the relationships between the classes of the system. Figure 12.7 shows how our classes `ATM` and `Withdrawal` relate to one another. For the moment, for simplicity, we choose to model only this subset of classes. We present a more complete class diagram later in this section. Notice that the rectangles representing classes in this diagram are not subdivided into compartments. The UML allows the suppression of class attributes and operations in this manner to create more readable diagrams, when appropriate. Such a diagram is said to be an **elided diagram**—one in which some information, such as the contents of the second and third compartments, is *not* modeled. We'll place information in these compartments in Sections 12.4–12.6.

**Fig. 12.7** | Class diagram showing an association among classes.

In Fig. 12.7, the solid line that connects the two classes represents an **association**—a relationship between classes. The numbers near each end of the line are **multiplicity** values, which indicate how many objects of each class participate in the association. In this case, following the line from left to right reveals that, at any given moment, one `ATM` object participates in an association with either zero or one `Withdrawal` objects—zero if the current user is not currently performing a transaction or has requested a different type of transaction, and one if the user has requested a withdrawal. The UML can model many types of multiplicity. Figure 12.8 lists and explains the multiplicity types.

| Symbol | Meaning                                |
|--------|----------------------------------------|
| 0      | None                                   |
| 1      | One                                    |
| $m$    | An integer value                       |
| 0..1   | Zero or one                            |
| $m, n$ | $m$ or $n$                             |
| $m..n$ | At least $m$ , but not more than $n$   |
| *      | Any nonnegative integer (zero or more) |
| 0..*   | Zero or more (identical to *)          |
| 1..*   | One or more                            |

**Fig. 12.8** | Multiplicity types.

An association can be named. For example, the word `Executes` above the line connecting classes `ATM` and `Withdrawal` in Fig. 12.7 indicates the name of that association. This part of the diagram reads “one object of class `ATM` executes zero or one objects of class `Withdrawal`.” Association names are *directional*, as indicated by the filled arrowhead—so it would be improper, for example, to read the preceding association from right to left as “zero or one objects of class `Withdrawal` execute one object of class `ATM`.”

The word `currentTransaction` at the `Withdrawal` end of the association line in Fig. 12.7 is a **role name**, identifying the role the `Withdrawal` object plays in its relationship with the `ATM`. A role name adds meaning to an association between classes by identifying the role a class plays in the context of an association. A class can play several roles in the same system. For example, in a school personnel system, a person may play the role of “professor” when relating to students. The same person may take on the role of “colleague” when participating in an association with another professor, and “coach” when coaching student athletes. In Fig. 12.7, the role name `currentTransaction` indicates that the `Withdrawal` object participating in the `Executes` association with an object of class `ATM` represents the transaction currently being processed by the `ATM`. In other contexts, a `Withdrawal` object may take on other roles (e.g., the “previous transaction”). Notice that we do not specify a role name for the `ATM` end of the `Executes` association. Role names in class diagrams are often omitted when the meaning of an association is clear without them.

In addition to indicating simple relationships, associations can specify more complex relationships, such as objects of one class being *composed of* objects of other classes. Consider a real-world automated teller machine. What “pieces” does a manufacturer put together to build a working `ATM`? Our requirements document tells us that the `ATM` is composed of a screen, a keypad, a cash dispenser and a deposit slot.

In Fig. 12.9, the **solid diamonds** attached to the `ATM` class’s association lines indicate that `ATM` has a **composition** relationship with classes `Screen`, `Keypad`, `CashDispenser` and `DepositSlot`. Composition implies a *whole/part relationship*. The class that has the composition symbol (the solid diamond) on its end of the association line is the *whole* (in this case, `ATM`), and the classes on the other end of the association lines are the *parts*—in this case, `Screen`, `Keypad`, `CashDispenser` and `DepositSlot`. The compositions in Fig. 12.9 indicate that an object of class `ATM` is formed from one object of class `Screen`, one object

of class `CashDispenser`, one object of class `Keypad` and one object of class `DepositSlot`. The ATM *has a* screen, a keypad, a cash dispenser and a deposit slot. (As we saw in Chapter 9, the *is-a* relationship defines inheritance. We'll see in Section 13.3 that there's a nice opportunity to use inheritance in the ATM system design.)

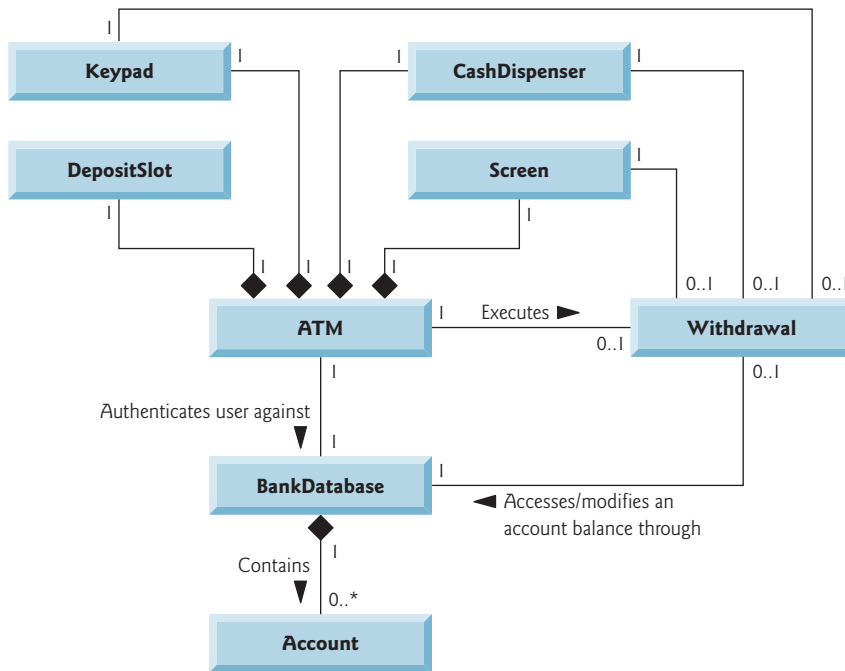

**Fig. 12.9** | Class diagram showing composition relationships.

According to the UML specification ([www.omg.org/technology/documents/formal/uml.htm](http://www.omg.org/technology/documents/formal/uml.htm)), composition relationships have the following properties:

1. Only one class in the relationship can represent the *whole* (i.e., the diamond can be placed on only *one* end of the association line). For example, either the screen is part of the ATM or the ATM is part of the screen, but the screen and the ATM cannot both represent the whole in the relationship.
2. The *parts* in the composition relationship exist only as long as the whole does, and the whole is responsible for the creation and destruction of its parts. For example, the act of constructing an ATM includes manufacturing its parts. Also, if the ATM is destroyed, its screen, keypad, cash dispenser and deposit slot are also destroyed.
3. A *part* may belong to only one *whole* at a time, although it may be removed and attached to another whole, which then assumes responsibility for the part.

The solid diamonds in our class diagrams indicate composition relationships that fulfill these properties. If a *has-a* relationship does not satisfy one or more of these criteria, the UML specifies that **hollow diamonds** be attached to the ends of association lines to indicate **aggregation**—a weaker form of composition. For example, a personal computer and a computer monitor participate in an aggregation relationship—the computer *has a* monitor, but the two parts can exist independently, and the same monitor can be attached to multiple computers at once, thus violating composition's second and third properties.

Figure 12.10 shows a class diagram for the ATM system. This diagram models most of the classes that we've identified, as well as the associations between them that we can infer from the requirements document. Classes `BalanceInquiry` and `Deposit` participate in associations similar to those of class `Withdrawal`, so we've chosen to omit them from this diagram to keep it simple. In Section 13.3, we expand our class diagram to include all the classes in the ATM system.

**Fig. 12.10** | Class diagram for the ATM system model.

Figure 12.10 presents a graphical model of ATM system’s structure. It includes classes BankDatabase and Account, and several associations that were not present in either Fig. 12.7 or Fig. 12.9. It shows that class ATM has a **one-to-one relationship** with class BankDatabase—one ATM object *authenticates users against* one BankDatabase object. In Fig. 12.10, we also model the fact that the bank’s database contains information about many accounts—one BankDatabase object participates in a *composition* relationship with zero or more Account objects. The multiplicity value 0..\* at the Account end of the association between class BankDatabase and class Account indicates that zero or more objects of class Account take part in the association. Class BankDatabase has a **one-to-many relationship** with class Account—the BankDatabase can contain many Accounts. Similarly, class Account has a **many-to-one relationship** with class BankDatabase—there can be many Accounts stored in the BankDatabase. Recall from Fig. 12.8 that the multiplicity value \* is identical to 0..\*. We include 0..\* in our class diagrams for clarity.

Figure 12.10 also indicates that at any given time 0 or 1 Withdrawal objects can exist. If the user is performing a withdrawal, “one object of class Withdrawal accesses/modifies an account balance through one object of class BankDatabase.” We could have created an association directly between class Withdrawal and class Account. The requirements document, however, states that the “ATM must interact with the bank’s account information database” to perform transactions. A bank account contains sensitive information, and systems engineers must always consider the security of personal data when designing a system. Thus, only the BankDatabase can access and manipulate an account directly. All other

parts of the system must interact with the database to retrieve or update account information (e.g., an account balance).

The class diagram in Fig. 12.10 also models associations between class `Withdrawal` and classes `Screen`, `CashDispenser` and `Keypad`. A withdrawal transaction includes prompting the user to choose a withdrawal amount, and receiving numeric input. These actions require the use of the screen and the keypad, respectively. Furthermore, dispensing cash to the user requires access to the cash dispenser.

Classes `BalanceInquiry` and `Deposit`, though not shown in Fig. 12.10, take part in several associations with the other classes of the ATM system. Like class `Withdrawal`, each of these classes associates with classes `ATM` and `BankDatabase`. An object of class `BalanceInquiry` also associates with an object of class `Screen` to display the balance of an account to the user. Class `Deposit` associates with classes `Screen`, `Keypad` and `DepositSlot`. Like withdrawals, deposit transactions require use of the screen and the keypad to display prompts and receive input, respectively. To receive deposit envelopes, an object of class `Deposit` accesses the deposit slot.

We've now identified the initial classes in our ATM system—we may discover others as we proceed with the design and implementation. In Section 12.4 we determine the attributes for each of these classes, and in Section 12.5 we use these attributes to examine how the system changes over time.

### Self-Review Exercises for Section 12.3

**12.4** Suppose we have a class `Car` that represents a car. Think of some of the different pieces that a manufacturer would put together to produce a whole car. Create a class diagram (similar to Fig. 12.9) that models some of the composition relationships of class `Car`.

**12.5** Suppose we have a class `File` that represents an electronic document in a standalone, non-networked computer represented by class `Computer`. What sort of association exists between class `Computer` and class `File`?

- Class `Computer` has a one-to-one relationship with class `File`.
- Class `Computer` has a many-to-one relationship with class `File`.
- Class `Computer` has a one-to-many relationship with class `File`.
- Class `Computer` has a many-to-many relationship with class `File`.

**12.6** State whether the following statement is *true* or *false*, and if *false*, explain why: A UML diagram in which a class's second and third compartments are not modeled is said to be an elided diagram.

**12.7** Modify the class diagram of Fig. 12.10 to include class `Deposit` instead of class `Withdrawal`.

## 12.4 Identifying Class Attributes

[*Note: This section can be taught after Chapter 4.*]

Classes have attributes (data) and operations (behaviors). Class attributes are implemented as fields, and class operations are implemented as methods. In this section, we determine many of the attributes needed in the ATM system. In Section 12.5 we examine how these attributes represent an object's state. In Section 12.6 we determine class operations.

### Identifying Attributes

Consider the attributes of some real-world objects: A person's attributes include height, weight and whether the person is left-handed, right-handed or ambidextrous. A radio's at-

tributes include its station, volume and AM or FM settings. A car’s attributes include its speedometer and odometer readings, the amount of gas in its tank and what gear it’s in. A personal computer’s attributes include its manufacturer (e.g., Dell, Sun, Apple or IBM), type of screen (e.g., LCD or CRT), main memory size and hard disk size.

We can identify many attributes of the classes in our system by looking for descriptive words and phrases in the requirements document. For each such word and phrase we find that plays a significant role in the ATM system, we create an attribute and assign it to one or more of the classes identified in Section 12.3. We also create attributes to represent any additional data that a class may need, as such needs become clear throughout the design process.

Figure 12.11 lists the words or phrases from the requirements document that describe each class. We formed this list by reading the requirements document and identifying any words or phrases that refer to characteristics of the classes in the system. For example, the requirements document describes the steps taken to obtain a “withdrawal amount,” so we list “amount” next to class `Withdrawal`.

| Class                       | Descriptive words and phrases              |
|-----------------------------|--------------------------------------------|
| <code>ATM</code>            | user is authenticated                      |
| <code>BalanceInquiry</code> | account number                             |
| <code>Withdrawal</code>     | account number<br>amount                   |
| <code>Deposit</code>        | account number<br>amount                   |
| <code>BankDatabase</code>   | <i>[no descriptive words or phrases]</i>   |
| <code>Account</code>        | account number<br>PIN<br>balance           |
| <code>Screen</code>         | <i>[no descriptive words or phrases]</i>   |
| <code>Keypad</code>         | <i>[no descriptive words or phrases]</i>   |
| <code>CashDispenser</code>  | begins each day loaded with 500 \$20 bills |
| <code>DepositSlot</code>    | <i>[no descriptive words or phrases]</i>   |

**Fig. 12.11** | Descriptive words and phrases from the ATM requirements document.

Figure 12.11 leads us to create one attribute of class `ATM`. Class `ATM` maintains information about the state of the ATM. The phrase “user is authenticated” describes a state of the ATM (we introduce states in Section 12.5), so we include `userAuthenticated` as a **Boolean attribute** (i.e., an attribute that has a value of either `true` or `false`) in class `ATM`. The `Boolean` attribute type in the UML is equivalent to the `boolean` type in Java. This attribute indicates whether the ATM has successfully authenticated the current user—`userAuthenticated` must be `true` for the system to allow the user to perform transactions and access account information. This attribute helps ensure the security of the data in the system.

Classes `BalanceInquiry`, `Withdrawal` and `Deposit` share one attribute. Each transaction involves an “account number” that corresponds to the account of the user making the

transaction. We assign an integer attribute `accountNumber` to each transaction class to identify the account to which an object of the class applies.

Descriptive words and phrases in the requirements document also suggest some differences in the attributes required by each transaction class. The requirements document indicates that to withdraw cash or deposit funds, users must input a specific “amount” of money to be withdrawn or deposited, respectively. Thus, we assign to classes `Withdrawal` and `Deposit` an attribute `amount` to store the value supplied by the user. The amounts of money related to a withdrawal and a deposit are defining characteristics of these transactions that the system requires for these transactions to take place. Class `BalanceInquiry`, however, needs no additional data to perform its task—it requires only an account number to indicate the account whose balance should be retrieved.

Class `Account` has several attributes. The requirements document states that each bank account has an “account number” and “PIN,” which the system uses for identifying accounts and authenticating users. We assign to class `Account` two integer attributes: `accountNumber` and `pin`. The requirements document also specifies that an account maintains a “balance” of the amount of money in the account and that money the user deposits does not become available for a withdrawal until the bank verifies the amount of cash in the deposit envelope, and any checks in the envelope clear. An account must still record the amount of money that a user deposits, however. Therefore, we decide that an account should represent a balance using two attributes: `availableBalance` and `totalBalance`. Attribute `availableBalance` tracks the amount of money that a user can withdraw from the account. Attribute `totalBalance` refers to the total amount of money that the user has “on deposit” (i.e., the amount of money available, plus the amount waiting to be verified or cleared). For example, suppose an ATM user deposits \$50.00 into an empty account. The `totalBalance` attribute would increase to \$50.00 to record the deposit, but the `availableBalance` would remain at \$0. [*Note:* We assume that the bank updates the `availableBalance` attribute of an `Account` some length of time after the ATM transaction occurs, in response to confirming that \$50 worth of cash or checks was found in the deposit envelope. We assume that this update occurs through a transaction that a bank employee performs using some piece of bank software other than the ATM. Thus, we do not discuss this transaction in our case study.]

Class `CashDispenser` has one attribute. The requirements document states that the cash dispenser “begins each day loaded with 500 \$20 bills.” The cash dispenser must keep track of the number of bills it contains to determine whether enough cash is on hand to satisfy withdrawal requests. We assign to class `CashDispenser` an integer attribute `count`, which is initially set to 500.

For real problems in industry, there’s no guarantee that requirements documents will be precise enough for the object-oriented systems designer to determine all the attributes or even all the classes. The need for additional classes, attributes and behaviors may become clear as the design process proceeds. As we progress through this case study, we will continue to add, modify and delete information about the classes in our system.

### *Modeling Attributes*

The class diagram in Fig. 12.12 lists some of the attributes for the classes in our system—the descriptive words and phrases in Fig. 12.11 lead us to identify these attributes. For simplicity, Fig. 12.12 does not show the associations among classes—we showed these in Fig. 12.10. This is a common practice of systems designers when designs are being devel-

oped. Recall from Section 12.3 that in the UML, a class's attributes are placed in the middle compartment of the class's rectangle. We list each attribute's name and type separated by a colon (:), followed in some cases by an equal sign (=) and an initial value.

Consider the `userAuthenticated` attribute of class `ATM`:

```
userAuthenticated : Boolean = false
```

This attribute declaration contains three pieces of information about the attribute. The **attribute name** is `userAuthenticated`. The **attribute type** is `Boolean`. In Java, an attribute can be represented by a primitive type, such as `boolean`, `int` or `double`, or a reference type like a class. We've chosen to model only primitive-type attributes in Fig. 12.12—we discuss the reasoning behind this decision shortly. The attribute types in Fig. 12.12 are in UML notation. We'll associate the types `Boolean`, `Integer` and `Double` in the UML diagram with the primitive types `boolean`, `int` and `double` in Java, respectively.

**Fig. 12.12** | Classes with attributes.

We can also indicate an initial value for an attribute. The `userAuthenticated` attribute in class `ATM` has an initial value of `false`. This indicates that the system initially does not consider the user to be authenticated. If an attribute has no initial value specified, only its name and type (separated by a colon) are shown. For example, the `accountNumber` attribute of class `BalanceInquiry` is an integer. Here we show no initial value, because the

value of this attribute is a number that we do not yet know. This number will be determined at execution time based on the account number entered by the current ATM user.

Figure 12.12 does not include attributes for classes `Screen`, `Keypad` and `DepositSlot`. These are important components of our system, for which our design process has not yet revealed any attributes. We may discover some, however, in the remaining phases of design or when we implement these classes in Java. This is perfectly normal.

### Software Engineering Observation 12.1

*At early stages in the design process, classes often lack attributes (and operations). Such classes should not be eliminated, however, because attributes (and operations) may become evident in the later phases of design and implementation.*

Figure 12.12 also does not include attributes for class `BankDatabase`. Recall that attributes in Java can be represented by either primitive types or reference types. We've chosen to include only primitive-type attributes in the class diagram in Fig. 12.12 (and in similar class diagrams throughout the case study). A reference-type attribute is modeled more clearly as an association between the class holding the reference and the class of the object to which the reference points. For example, the class diagram in Fig. 12.10 indicates that class `BankDatabase` participates in a composition relationship with zero or more `Account` objects. From this composition, we can determine that when we implement the ATM system in Java, we'll be required to create an attribute of class `BankDatabase` to hold references to zero or more `Account` objects. Similarly, we can determine reference-type attributes of class `ATM` that correspond to its composition relationships with classes `Screen`, `Keypad`, `CashDispenser` and `DepositSlot`. These composition-based attributes would be redundant if modeled in Fig. 12.12, because the compositions modeled in Fig. 12.10 already convey the fact that the database contains information about zero or more accounts and that an ATM is composed of a screen, keypad, cash dispenser and deposit slot. Software developers typically model these whole/part relationships as compositions rather than as attributes required to implement the relationships.

The class diagram in Fig. 12.12 provides a solid basis for the structure of our model, but the diagram is not complete. In Section 12.5 we identify the states and activities of the objects in the model, and in Section 12.6 we identify the operations that the objects perform. As we present more of the UML and object-oriented design, we'll continue to strengthen the structure of our model.

## Self-Review Exercises for Section 12.4

**12.8** We typically identify the attributes of the classes in our system by analyzing the \_\_\_\_\_ in the requirements document.

- nouns and noun phrases
- descriptive words and phrases
- verbs and verb phrases
- All of the above.

**12.9** Which of the following is *not* an attribute of an airplane?

- length
- wingspan
- fly
- number of seats

**12.10** Describe the meaning of the following attribute declaration of class `CashDispenser` in the class diagram in Fig. 12.12:

```
count : Integer = 500
```

## 12.5 Identifying Objects' States and Activities

[*Note: This section can be taught after Chapter 5.*]

In Section 12.4, we identified many of the class attributes needed to implement the ATM system and added them to the class diagram in Fig. 12.12. We now show how these attributes represent an object's state. We identify some key states that our objects may occupy and discuss how objects *change state* in response to various events occurring in the system. We also discuss the workflow, or **activities**, that objects perform in the ATM system, and we present the activities of `BalanceInquiry` and `Withdrawal` transaction objects.

### State Machine Diagrams

Each object in a system goes through a series of states. An object's state is indicated by the values of its attributes at a given time. **State machine diagrams** (commonly called **state diagrams**) model several states of an object and show under what circumstances the object changes state. Unlike the class diagrams presented in earlier case study sections, which focused primarily on the system's *structure*, state diagrams model some of the system's *behavior*.

Figure 12.13 is a simple state diagram that models some of the states of an object of class `ATM`. The UML represents each state in a state diagram as a **rounded rectangle** with the name of the state placed inside it. A **solid circle** with an attached stick ( $\Rightarrow$ ) arrowhead designates the **initial state**. Recall that we modeled this state information as the `Boolean` attribute `userAuthenticated` in the class diagram of Fig. 12.12. This attribute is initialized to `false`, or the “User not authenticated” state, according to the state diagram.

**Fig. 12.13** | State diagram for the ATM object.

The arrows with stick ( $\Rightarrow$ ) arrowhead indicate **transitions** between states. An object can transition from one state to another in response to various *events* that occur in the system. The name or description of the event that causes a transition is written near the line that corresponds to the transition. For example, the ATM object changes from the “User not authenticated” to the “User authenticated” state after the database authenticates the user. Recall from the requirements document that the database authenticates a user by comparing the account number and PIN entered by the user with those of an account in the database. If the user has entered a valid account number and the correct PIN, the ATM object transitions to the “User authenticated” state and changes its `userAuthenticated` attribute to a value of `true`. When the user exits the system by choosing the “exit” option from the main menu, the ATM object returns to the “User not authenticated” state.

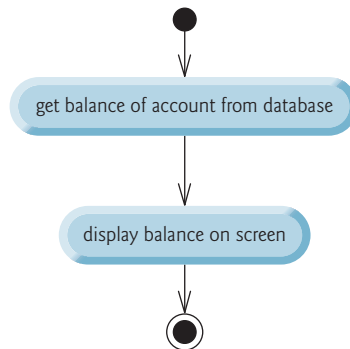

### Software Engineering Observation 12.2

Software designers do not generally create state diagrams showing every possible state and state transition for all attributes—there are simply too many of them. State diagrams typically show only key states and state transitions.

### Activity Diagrams

Like a state diagram, an activity diagram models aspects of system behavior. Unlike a state diagram, an activity diagram models an object's **workflow** (sequence of events) during program execution. An activity diagram models the **actions** the object will perform and in what *order*. The activity diagram in Fig. 12.14 models the actions involved in executing a balance-inquiry transaction. We assume that a `BalanceInquiry` object has already been initialized and assigned a valid account number (that of the current user), so the object knows which balance to retrieve. The diagram includes the actions that occur after the user selects a balance inquiry from the main menu and before the ATM returns the user to the main menu—a `BalanceInquiry` object does not perform or initiate these actions, so we do not model them here. The diagram begins with retrieving the balance of the account from the database. Next, the `BalanceInquiry` displays the balance on the screen. This action completes the execution of the transaction. Recall that we've chosen to represent an account balance as both the `availableBalance` and `totalBalance` attributes of class `Account`, so the actions modeled in Fig. 12.14 refer to the retrieval and display of *both* balance attributes.

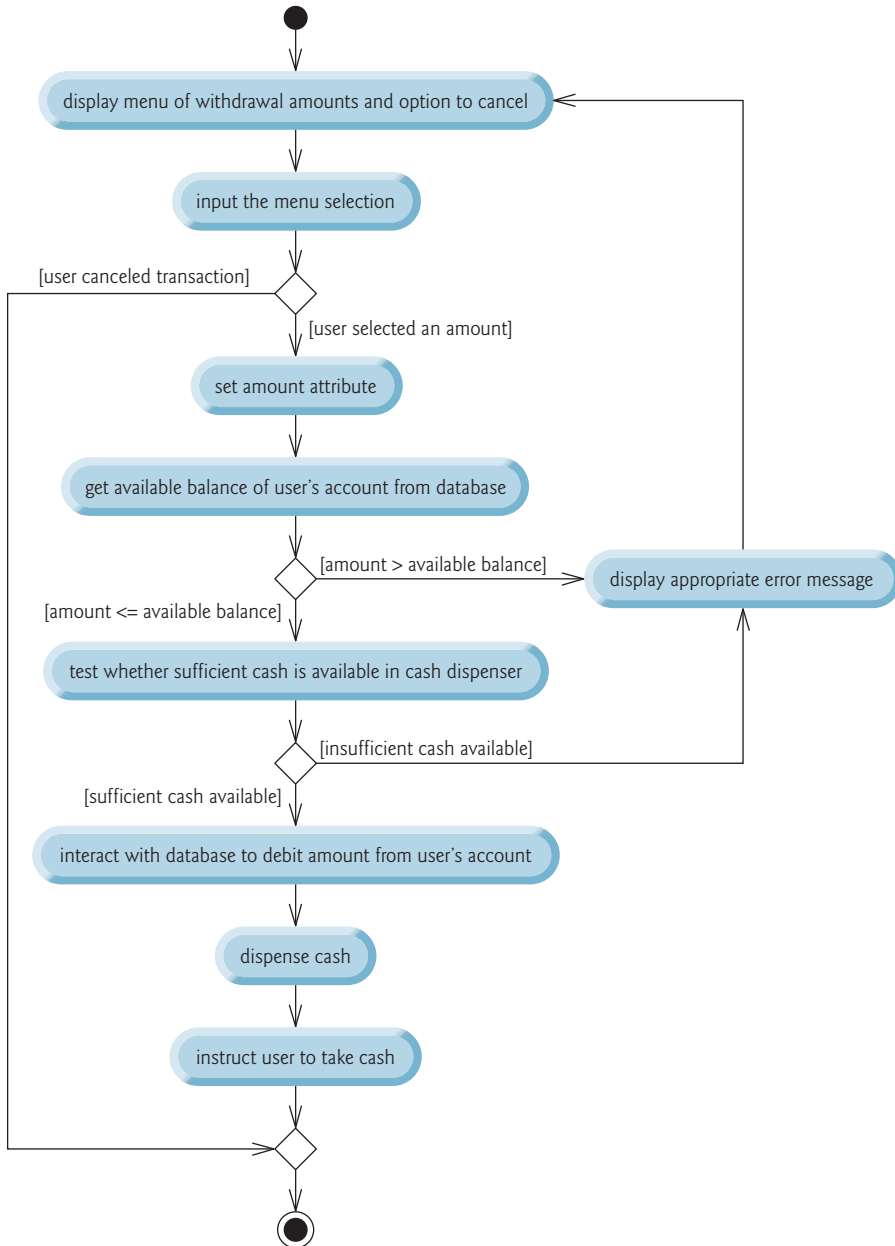

**Fig. 12.14** | Activity diagram for a `BalanceInquiry` object.

The UML represents an action in an activity diagram as an action state modeled by a rectangle with its left and right sides replaced by arcs curving outward. Each action state contains an *action expression*—for example, “get balance of account from database”—that specifies an action to be performed. An arrow with a stick ( $\Rightarrow$ ) arrowhead connects two action states, indicating the order in which the actions represented by the action states occur. The solid circle (at the top of Fig. 12.14) represents the activity's *initial state*—the beginning of the workflow before the object performs the modeled actions. In this case, the transaction first executes the “get balance of account from database” action expression. The transaction then displays *both* balances on the screen. The solid circle enclosed in an open circle (at the bottom of Fig. 12.14) represents the *final state*—the end of the work-

flow after the object performs the modeled actions. We used UML activity diagrams to illustrate the flow of control for the control statements presented in Chapters 4–5.

Figure 12.15 shows an activity diagram for a withdrawal transaction. We assume that a `Withdrawal` object has been assigned a valid account number. We do not model the user

**Fig. 12.15** | Activity diagram for a withdrawal transaction.

selecting a withdrawal from the main menu or the ATM returning the user to the main menu because these are not actions performed by a `Withdrawal` object. The transaction first displays a menu of standard withdrawal amounts (shown in Fig. 12.3) and an option to cancel the transaction. The transaction then receives a menu selection from the user. The activity flow now arrives at a decision (a fork indicated by the small diamond symbol). This point determines the next action based on the associated guard condition (in square brackets next to the transition), which states that the transition occurs if this guard condition is met. If the user cancels the transaction by choosing the “cancel” option from the menu, the activity flow immediately skips to the final state. Note the merge (indicated by the small diamond symbol) where the cancellation flow of activity joins the main flow of activity before reaching the activity’s final state. If the user selects a withdrawal amount from the menu, `Withdrawal` sets `amount` (an attribute originally modeled in Fig. 12.12) to the value chosen by the user.

After setting the withdrawal amount, the transaction retrieves the available balance of the user’s account (i.e., the `availableBalance` attribute of the user’s `Account` object) from the database. The activity flow then arrives at another decision. If the requested withdrawal amount exceeds the user’s available balance, the system displays an appropriate error message informing the user of the problem, then returns to the beginning of the activity diagram and prompts the user to input a new amount. If the requested withdrawal amount is less than or equal to the user’s available balance, the transaction proceeds. The transaction next tests whether the cash dispenser has enough cash remaining to satisfy the withdrawal request. If it does not, the transaction displays an appropriate error message, then returns to the beginning of the activity diagram and prompts the user to choose a new amount. If sufficient cash is available, the transaction interacts with the database to debit the withdrawal amount from the user’s account (i.e., subtract the amount from *both* the `availableBalance` and `totalBalance` attributes of the user’s `Account` object). The transaction then dispenses the desired amount of cash and instructs the user to take it. Finally, the main flow of activity merges with the cancellation flow of activity before reaching the final state.

We’ve taken the first steps in modeling the ATM software system’s behavior and have shown how an object’s attributes participate in performing the object’s activities. In Section 12.6, we investigate the behaviors for all classes to give a more accurate interpretation of the system behavior by filling in the third compartments of the classes in our class diagram.

## Self-Review Exercises for Section 12.5

**12.11** State whether the following statement is *true* or *false*, and if *false*, explain why: State diagrams model structural aspects of a system.

**12.12** An activity diagram models the \_\_\_\_\_ that an object performs and the order in which it performs them.

- a) actions
- b) attributes
- c) states
- d) state transitions

**12.13** Based on the requirements document, create an activity diagram for a deposit transaction.

## 12.6 Identifying Class Operations

[*Note:* This section can be taught after Chapter 6.]

In this section, we determine some of the class operations (or behaviors) needed to implement the ATM system. An operation is a service that objects of a class provide to clients (users) of the class. Consider the operations of some real-world objects. A radio's operations include setting its station and volume (typically invoked by a person's adjusting the radio's controls). A car's operations include accelerating (invoked by the driver's pressing the accelerator pedal), decelerating (invoked by the driver's pressing the brake pedal or releasing the gas pedal), turning and shifting gears. Software objects can offer operations as well—for example, a software graphics object might offer operations for drawing a circle, drawing a line, drawing a square and the like. A spreadsheet software object might offer operations like printing the spreadsheet, totaling the elements in a row or column and graphing information in the spreadsheet as a bar chart or pie chart.

We can derive many of the class operations by examining the key *verbs and verb phrases* in the requirements document. We then relate these verbs and verb phrases to classes in our system (Fig. 12.16). The verb phrases in Fig. 12.16 help us determine the operations of each class.

| Class          | Verbs and verb phrases                                                                                                                 |
|----------------|----------------------------------------------------------------------------------------------------------------------------------------|
| ATM            | executes financial transactions                                                                                                        |
| BalanceInquiry | <i>[none in the requirements document]</i>                                                                                             |
| Withdrawal     | <i>[none in the requirements document]</i>                                                                                             |
| Deposit        | <i>[none in the requirements document]</i>                                                                                             |
| BankDatabase   | authenticates a user, retrieves an account balance, credits a deposit amount to an account, debits a withdrawal amount from an account |
| Account        | retrieves an account balance, credits a deposit amount to an account, debits a withdrawal amount from an account                       |
| Screen         | displays a message to the user                                                                                                         |
| Keypad         | receives numeric input from the user                                                                                                   |
| CashDispenser  | dispenses cash, indicates whether it contains enough cash to satisfy a withdrawal request                                              |
| DepositSlot    | receives a deposit envelope                                                                                                            |

**Fig. 12.16** | Verbs and verb phrases for each class in the ATM system.

### *Modeling Operations*

To identify operations, we examine the verb phrases listed for each class in Fig. 12.16. The “executes financial transactions” phrase associated with class ATM implies that class ATM instructs transactions to execute. Therefore, classes `BalanceInquiry`, `Withdrawal` and `Deposit` each need an operation to provide this service to the ATM. We place this operation (which we’ve named `execute`) in the third compartment of the three transaction classes in the updated class diagram of Fig. 12.17. During an ATM session, the ATM object will invoke these transaction operations as necessary.

**Fig. 12.17** | Classes in the ATM system with attributes and operations.

The UML represents operations (that is, methods) by listing the operation name, followed by a comma-separated list of parameters in parentheses, a colon and the return type:

*operationName( parameter1, parameter2, ..., parameterN ) : return type*

Each parameter in the comma-separated parameter list consists of a parameter name, followed by a colon and the parameter type:

*parameterName : parameterType*

For the moment, we do not list the parameters of our operations—we’ll identify and model some of them shortly. For some of the operations, we do not yet know the return types, so we also omit them from the diagram. These omissions are perfectly normal at this point. As our design and implementation proceed, we’ll add the remaining return types.

### *Authenticating a User*

Figure 12.16 lists the phrase “authenticates a user” next to class BankDatabase—the database is the object that contains the account information necessary to determine whether

the account number and PIN entered by a user match those of an account held at the bank. Therefore, class `BankDatabase` needs an operation that provides an authentication service to the ATM. We place the operation `authenticateUser` in the third compartment of class `BankDatabase` (Fig. 12.17). However, an object of class `Account`, not class `BankDatabase`, stores the account number and PIN that must be accessed to authenticate a user, so class `Account` must provide a service to validate a PIN obtained through user input against a PIN stored in an `Account` object. Therefore, we add a `validatePIN` operation to class `Account`. We specify a return type of `Boolean` for the `authenticateUser` and `validatePIN` operations. Each operation returns a value indicating either that the operation was successful in performing its task (i.e., a return value of `true`) or that it was not (i.e., a return value of `false`).

### *Other BankDatabase and Account Operations*

Figure 12.16 lists several additional verb phrases for class `BankDatabase`: “retrieves an account balance,” “credits a deposit amount to an account” and “debits a withdrawal amount from an account.” Like “authenticates a user,” these remaining phrases refer to services that the database must provide to the ATM, because the database holds all the account data used to authenticate a user and perform ATM transactions. However, objects of class `Account` actually perform the operations to which these phrases refer. Thus, we assign an operation to both class `BankDatabase` and class `Account` to correspond to each of these phrases. Recall from Section 12.3 that, because a bank account contains sensitive information, we do not allow the ATM to access accounts directly. The database acts as an intermediary between the ATM and the account data, thus preventing unauthorized access. As we’ll see in Section 12.7, class `ATM` invokes the operations of class `BankDatabase`, each of which in turn invokes the operation with the same name in class `Account`.

### *Getting the Balances*

The phrase “retrieves an account balance” suggests that classes `BankDatabase` and `Account` each need a `getBalance` operation. However, recall that we created *two* attributes in class `Account` to represent a balance—`availableBalance` and `totalBalance`. A balance inquiry requires access to *both* balance attributes so that it can display them to the user, but a withdrawal needs to check *only* the value of `availableBalance`. To allow objects in the system to obtain each balance attribute individually, we add operations `getAvailableBalance` and `getTotalBalance` to the third compartment of classes `BankDatabase` and `Account` (Fig. 12.17). We specify a return type of `Double` for these operations because the balance attributes they retrieve are of type `Double`.

### *Crediting and Debiting an Account*

The phrases “credits a deposit amount to an account” and “debits a withdrawal amount from an account” indicate that classes `BankDatabase` and `Account` must perform operations to update an account during a deposit and withdrawal, respectively. We therefore assign `credit` and `debit` operations to classes `BankDatabase` and `Account`. You may recall that crediting an account (as in a deposit) adds an amount only to the `totalBalance` attribute. Debiting an account (as in a withdrawal), on the other hand, subtracts the amount from *both* balance attributes. We hide these implementation details inside class `Account`. This is a good example of encapsulation and information hiding.

### *Deposit Confirmations Performed by Another Banking System*

If this were a real ATM system, classes `BankDatabase` and `Account` would also provide a set of operations to allow another banking system to update a user's account balance after either confirming or rejecting all or part of a deposit. Operation `confirmDepositAmount`, for example, would add an amount to the `availableBalance` attribute, thus making deposited funds available for withdrawal. Operation `rejectDepositAmount` would subtract an amount from the `totalBalance` attribute to indicate that a specified amount, which had recently been deposited through the ATM and added to the `totalBalance`, was not found in the deposit envelope. The bank would invoke this operation after determining either that the user failed to include the correct amount of cash or that any checks did not clear (i.e., they “bounced”). While adding these operations would make our system more complete, we do *not* include them in our class diagrams or our implementation because they're beyond the scope of the case study.

### *Displaying Messages*

Class `Screen` “displays a message to the user” at various times in an ATM session. All visual output occurs through the screen of the ATM. The requirements document describes many types of messages (e.g., a welcome message, an error message, a thank you message) that the screen displays to the user. The requirements document also indicates that the screen displays prompts and menus to the user. However, a prompt is really just a message describing what the user should input next, and a menu is essentially a type of prompt consisting of a series of messages (i.e., menu options) displayed consecutively. Therefore, rather than assign class `Screen` an individual operation to display each type of message, prompt and menu, we simply create one operation that can display any message specified by a parameter. We place this operation (`displayMessage`) in the third compartment of class `Screen` in our class diagram (Fig. 12.17). We do not worry about the parameter of this operation at this time—we model it later in this section.

### *Keyboard Input*

From the phrase “receives numeric input from the user” listed by class `Keypad` in Fig. 12.16, we conclude that class `Keypad` should perform a `getInput` operation. Because the ATM's keypad, unlike a computer keyboard, contains only the numbers 0–9, we specify that this operation returns an integer value. Recall from the requirements document that in different situations the user may be required to enter a different type of number (e.g., an account number, a PIN, the number of a menu option, a deposit amount as a number of cents). Class `Keypad` simply obtains a numeric value for a client of the class—it does not determine whether the value meets any specific criteria. Any class that uses this operation must verify that the user entered an appropriate number in a given situation, then respond accordingly (i.e., display an error message via class `Screen`). [*Note:* When we implement the system, we simulate the ATM's keypad with a computer keyboard, and for simplicity we assume that the user does not enter nonnumeric input using keys on the computer keyboard that do not appear on the ATM's keypad.]

### *Dispensing Cash*

Figure 12.16 lists “dispenses cash” for class `CashDispenser`. Therefore, we create operation `dispenseCash` and list it under class `CashDispenser` in Fig. 12.17. Class `CashDispenser` also “indicates whether it contains enough cash to satisfy a withdrawal request.”

Thus, we include `isSufficientCashAvailable`, an operation that returns a value of UML type `Boolean`, in class `CashDispenser`.

Figure 12.16 also lists “receives a deposit envelope” for class `DepositSlot`. The deposit slot must indicate whether it received an envelope, so we place an operation `isEnvelopeReceived`, which returns a `Boolean` value, in the third compartment of class `DepositSlot`. [Note: A real hardware deposit slot would most likely send the ATM a signal to indicate that an envelope was received. We simulate this behavior, however, with an operation in class `DepositSlot` that class `ATM` can invoke to find out whether the deposit slot received an envelope.]

### Class ATM

We do not list any operations for class `ATM` at this time. We’re not yet aware of any services that class `ATM` provides to other classes in the system. When we implement the system with Java code, however, operations of this class, and additional operations of the other classes in the system, may emerge.

### Identifying and Modeling Operation Parameters for Class `BankDatabase`

So far, we’ve not been concerned with the *parameters* of our operations—we’ve attempted to gain only a basic understanding of the operations of each class. Let’s now take a closer look at some operation parameters. We identify an operation’s parameters by examining what data the operation requires to perform its assigned task.

Consider `BankDatabase`’s `authenticateUser` operation. To authenticate a user, this operation must know the account number and PIN supplied by the user. So we specify that `authenticateUser` takes integer parameters `userAccountNumber` and `userPIN`, which the operation must compare to an `Account` object’s account number and PIN in the database. We prefix these parameter names with “user” to avoid confusion between the operation’s parameter names and class `Account`’s attribute names. We list these parameters in the class diagram in Fig. 12.18 that models only class `BankDatabase`. [Note: It’s perfectly normal to model only one class. In this case, we’re examining the parameters of this one class, so we omit the other classes. In class diagrams later in the case study, in which parameters are no longer the focus of our attention, we omit these parameters to save space. Remember, however, that the operations listed in these diagrams still have parameters.]

**Fig. 12.18** | Class `BankDatabase` with operation parameters.

Recall that the UML models each parameter in an operation’s comma-separated parameter list by listing the parameter name, followed by a colon and the parameter type

(in UML notation). Figure 12.18 thus specifies that operation `authenticateUser` takes two parameters—`userAccountNumber` and `userPIN`, both of type `Integer`. When we implement the system in Java, we'll represent these parameters with `int` values.

Class `BankDatabase` operations `getAvailableBalance`, `getTotalBalance`, `credit` and `debit` also each require a `userAccountNumber` parameter to identify the account to which the database must apply the operations, so we include these parameters in the class diagram of Fig. 12.18. In addition, operations `credit` and `debit` each require a `Double` parameter `amount` to specify the amount of money to be credited or debited, respectively.

### *Identifying and Modeling Operation Parameters for Class Account*

Figure 12.19 models class `Account`'s operation parameters. Operation `validatePIN` requires only a `userPIN` parameter, which contains the user-specified PIN to be compared with the account's PIN. Like their `BankDatabase` counterparts, operations `credit` and `debit` in class `Account` each require a `Double` parameter `amount` that indicates the amount of money involved in the operation. Operations `getAvailableBalance` and `getTotalBalance` in class `Account` require no additional data to perform their tasks. Class `Account`'s operations do *not* require an account-number parameter to distinguish between `Accounts`, because these operations can be invoked only on a specific `Account` object.

**Fig. 12.19** | Class `Account` with operation parameters.

### *Identifying and Modeling Operation Parameters for Class Screen*

Figure 12.20 models class `Screen` with a parameter specified for operation `displayMessage`. This operation requires only a `String` parameter `message` that indicates the text to be displayed. Recall that the parameter types listed in our class diagrams are in UML notation, so the `String` type listed in Fig. 12.20 refers to the UML type. When we implement the system in Java, we'll use the Java class `String` to represent this parameter.

**Fig. 12.20** | Class `Screen` with operation parameters.

### Identifying and Modeling Operation Parameters for Class `CashDispenser`

Figure 12.21 specifies that operation `dispenseCash` of class `CashDispenser` takes a `Double` parameter `amount` to indicate the amount of cash (in dollars) to be dispensed. Operation `isSufficientCashAvailable` also takes a `Double` parameter `amount` to indicate the amount of cash in question.

**Fig. 12.21** | Class `CashDispenser` with operation parameters.

### Identifying and Modeling Operation Parameters for Other Classes

We do not discuss parameters for operation `execute` of classes `BalanceInquiry`, `Withdrawal` and `Deposit`, operation `getInput` of class `Keypad` and operation `isEnvelopeReceived` of class `DepositSlot`. At this point in our design process, we cannot determine whether these operations require additional data, so we leave their parameter lists empty. Later, we may decide to add parameters.

In this section, we've determined many of the operations performed by the classes in the ATM system. We've identified the parameters and return types of some of the operations. As we continue our design process, the number of operations belonging to each class may vary—we might find that new operations are needed or that some current operations are unnecessary. We also might determine that some of our class operations need additional parameters and different return types, or that some parameters are unnecessary or require different types.

## Self-Review Exercises for Section 12.6

**12.14** Which of the following is *not* a behavior?

- reading data from a file
- printing output
- text output
- obtaining input from the user

**12.15** If you were to add to the ATM system an operation that returns the amount attribute of class `Withdrawal`, how and where would you specify this operation in the class diagram of Fig. 12.17?

**12.16** Describe the meaning of the following operation listing that might appear in a class diagram for an object-oriented design of a calculator:

```
add( x : Integer, y : Integer ) : Integer
```

## 12.7 Indicating Collaboration Among Objects

[*Note:* This section can be taught after Chapter 7.]

In this section, we concentrate on the collaborations (interactions) among objects. When two objects communicate with each other to accomplish a task, they're said to **collaborate**—objects do this by invoking one another's operations. A **collaboration** consists of an

object of one class sending a **message** to an object of another class. Messages are sent in Java via method calls.

In Section 12.6, we determined many of the operations of the system's classes. Now, we concentrate on the messages that invoke these operations. To identify the collaborations in the system, we return to the requirements document in Section 12.2. Recall that this document specifies the range of activities that occur during an ATM session (e.g., authenticating a user, performing transactions). The steps used to describe how the system must perform each of these tasks are our first indication of the collaborations in our system. As we proceed through this section and Chapter 13, we may discover additional collaborations.

### *Identifying the Collaborations in a System*

We identify the collaborations in the system by carefully reading the sections of the requirements document that specify what the ATM should do to authenticate a user and to perform each transaction type. For each action or step described, we decide which objects in our system must interact to achieve the desired result. We identify one object as the sending object and another as the receiving object. We then select one of the receiving object's operations (identified in Section 12.6) that must be invoked by the sending object to produce the proper behavior. For example, the ATM displays a welcome message when idle. We know that an object of class `Screen` displays a message to the user via its `displayMessage` operation. Thus, we decide that the system can display a welcome message by employing a collaboration between the ATM and the `Screen` in which the ATM sends a `displayMessage` message to the `Screen` by invoking the `displayMessage` operation of class `Screen`. [Note: To avoid repeating the phrase "an object of class..." we refer to an object by using its class name preceded by an article (e.g., "a," "an" or "the")—for example, "the ATM" refers to an object of class `ATM`.]

Figure 12.22 lists the collaborations that can be derived from the requirements document. For each sending object, we list the collaborations in the order in which they first occur during an ATM session (i.e., the order in which they're discussed in the requirements document). We list each collaboration involving a unique sender, message and recipient only once, even though the collaborations may occur at several different times throughout an ATM session. For example, the first row in Fig. 12.22 indicates that the ATM collaborates with the `Screen` whenever the ATM needs to display a message to the user.

Let's consider the collaborations in Fig. 12.22. Before allowing a user to perform any transactions, the ATM must prompt the user to enter an account number, then to enter a PIN. It accomplishes these tasks by sending a `displayMessage` message to the `Screen`. Both actions refer to the same collaboration between the ATM and the `Screen`, which is already listed in Fig. 12.22. The ATM obtains input in response to a prompt by sending a `getInput` message to the `Keypad`. Next, the ATM must determine whether the user-specified account number and PIN match those of an account in the database. It does so by sending an `authenticateUser` message to the `BankDatabase`. Recall that the `BankDatabase` cannot authenticate a user directly—only the user's `Account` (i.e., the `Account` that contains the account number specified by the user) can access the user's PIN on record to authenticate the user. Figure 12.22 therefore lists a collaboration in which the `BankDatabase` sends a `validatePIN` message to an `Account`.

After the user is authenticated, the ATM displays the main menu by sending a series of `displayMessage` messages to the `Screen` and obtains input containing a menu selection by sending a `getInput` message to the `Keypad`. We've already accounted for these collab-

orations, so we do not add anything to Fig. 12.22. After the user chooses a type of transaction to perform, the ATM executes the transaction by sending an execute message to an object of the appropriate transaction class (i.e., a `BalanceInquiry`, a `Withdrawal` or a `Deposit`). For example, if the user chooses to perform a balance inquiry, the ATM sends an execute message to a `BalanceInquiry`.

| An object of class... | sends the message...                   | to an object of class... |
|-----------------------|----------------------------------------|--------------------------|
| ATM                   | <code>displayMessage</code>            | Screen                   |
|                       | <code>getInput</code>                  | Keypad                   |
|                       | <code>authenticateUser</code>          | BankDatabase             |
|                       | <code>execute</code>                   | BalanceInquiry           |
|                       | <code>execute</code>                   | Withdrawal               |
|                       | <code>execute</code>                   | Deposit                  |
| BalanceInquiry        | <code>getAvailableBalance</code>       | BankDatabase             |
|                       | <code>getTotalBalance</code>           | BankDatabase             |
|                       | <code>displayMessage</code>            | Screen                   |
| Withdrawal            | <code>displayMessage</code>            | Screen                   |
|                       | <code>getInput</code>                  | Keypad                   |
|                       | <code>getAvailableBalance</code>       | BankDatabase             |
|                       | <code>isSufficientCashAvailable</code> | CashDispenser            |
|                       | <code>debit</code>                     | BankDatabase             |
|                       | <code>dispenseCash</code>              | CashDispenser            |
| Deposit               | <code>displayMessage</code>            | Screen                   |
|                       | <code>getInput</code>                  | Keypad                   |
|                       | <code>isEnvelopeReceived</code>        | DepositSlot              |
|                       | <code>credit</code>                    | BankDatabase             |
| BankDatabase          | <code>validatePIN</code>               | Account                  |
|                       | <code>getAvailableBalance</code>       | Account                  |
|                       | <code>getTotalBalance</code>           | Account                  |
|                       | <code>debit</code>                     | Account                  |
|                       | <code>credit</code>                    | Account                  |

**Fig. 12.22** | Collaborations in the ATM system.

Further examination of the requirements document reveals the collaborations involved in executing each transaction type. A `BalanceInquiry` retrieves the amount of money available in the user's account by sending a `getAvailableBalance` message to the `BankDatabase`, which responds by sending a `getAvailableBalance` message to the user's `Account`. Similarly, the `BalanceInquiry` retrieves the amount of money on deposit by sending a `getTotalBalance` message to the `BankDatabase`, which sends the same message to the user's `Account`. To display both parts of the user's account balance at the same time, the `BalanceInquiry` sends a `displayMessage` message to the `Screen`.

A `Withdrawal` responds to an `execute` message by sending `displayMessage` messages to the `Screen` to display a menu of standard withdrawal amounts (i.e., \$20, \$40, \$60, \$100, \$200). The `Withdrawal` sends a `getInput` message to the `Keypad` to obtain the user's selection. Next, the `Withdrawal` determines whether the requested amount is less than or equal

to the user's account balance. The `Withdrawal` can obtain the amount of money available by sending a `getAvailableBalance` message to the `BankDatabase`. The `Withdrawal` then tests whether the cash dispenser contains enough cash by sending an `isSufficientCashAvailable` message to the `CashDispenser`. A `Withdrawal` sends a debit message to the `BankDatabase` to decrease the user's account balance. The `BankDatabase` in turn sends the same message to the appropriate `Account`, which decreases both the `totalBalance` and the `availableBalance`. To dispense the requested amount of cash, the `Withdrawal` sends a `dispenseCash` message to the `CashDispenser`. Finally, the `Withdrawal` sends a `displayMessage` message to the `Screen`, instructing the user to take the cash.

A `Deposit` responds to an `execute` message first by sending a `displayMessage` message to the `Screen` to prompt the user for a deposit amount. The `Deposit` sends a `getInput` message to the `Keypad` to obtain the user's input. The `Deposit` then sends a `displayMessage` message to the `Screen` to tell the user to insert a deposit envelope. To determine whether the deposit slot received an incoming deposit envelope, the `Deposit` sends an `isEnvelopeReceived` message to the `DepositSlot`. The `Deposit` updates the user's account by sending a `credit` message to the `BankDatabase`, which subsequently sends a `credit` message to the user's `Account`. Recall that crediting funds to an `Account` increases the `totalBalance` but not the `availableBalance`.

### Interaction Diagrams

Now that we've identified possible collaborations between our ATM system's objects, let's graphically model these interactions using the UML. The UML provides several types of **interaction diagrams** that model the behavior of a system by modeling how objects interact. The **communication diagram** emphasizes *which objects* participate in collaborations. Like the communication diagram, the **sequence diagram** shows collaborations among objects, but it emphasizes *when* messages are sent between objects *over time*.

### Communication Diagrams

Figure 12.23 shows a communication diagram that models the ATM executing a `BalanceInquiry`. Objects are modeled in the UML as rectangles containing names in the form `objectName : ClassName`. In this example, which involves only one object of each type, we disregard the object name and list only a colon followed by the class name. [Note: Specifying each object's name in a communication diagram is recommended when modeling multiple objects of the same type.] Communicating objects are connected with solid lines, and messages are passed between objects along these lines in the direction shown by arrows. The name of the message, which appears next to the arrow, is the name of an operation (i.e., a method in Java) belonging to the receiving object—think of the name as a “service” that the receiving object provides to sending objects (its clients).

**Fig. 12.23** | Communication diagram of the ATM executing a balance inquiry.

The solid filled arrow represents a message—or **synchronous call**—in the UML and a method call in Java. This arrow indicates that the flow of control is from the sending object

(the ATM) to the receiving object (a `BalanceInquiry`). Since this is a synchronous call, the sending object can't send another message, or do anything at all, until the receiving object processes the message and returns control to the sending object. The sender just waits. In Fig. 12.23, the ATM calls `BalanceInquiry` method `execute` and can't send another message until `execute` has finished and returns control to the ATM. [Note: If this were an **asynchronous call**, represented by a stick ( $\Rightarrow$ ) arrowhead, the sending object would not have to wait for the receiving object to return control—it would continue sending additional messages immediately following the asynchronous call. Asynchronous calls are implemented in Java using a technique called multithreading, which is discussed in Chapter 26.]

### Sequence of Messages in a Communication Diagram

Figure 12.24 shows a communication diagram that models the interactions among system objects when an object of class `BalanceInquiry` executes. We assume that the object's `accountNumber` attribute contains the account number of the current user. The collaborations in Fig. 12.24 begin after the ATM sends an `execute` message to a `BalanceInquiry` (i.e., the interaction modeled in Fig. 12.23). The number to the left of a message name indicates the order in which the message is passed. The **sequence of messages** in a communication diagram progresses in numerical order from least to greatest. In this diagram, the numbering starts with message 1 and ends with message 3. The `BalanceInquiry` first sends a `getAvailableBalance` message to the `BankDatabase` (message 1), then sends a `getTotalBalance` message to the `BankDatabase` (message 2). Within the parentheses following a message name, we can specify a comma-separated list of the names of the parameters sent with the message (i.e., arguments in a Java method call)—the `BalanceInquiry` passes attribute `accountNumber` with its messages to the `BankDatabase` to indicate which Account's balance information to retrieve. Recall from Fig. 12.18 that operations `getAvailableBalance` and `getTotalBalance` of class `BankDatabase` each require a parameter to identify an account. The `BalanceInquiry` next displays the `availableBalance` and the `totalBalance` to the user by passing a `displayMessage` message to the `Screen` (message 3) that includes a parameter indicating the message to be displayed.

**Fig. 12.24** | Communication diagram for executing a balance inquiry.

Figure 12.24 models two additional messages passing from the BankDatabase to an Account (message 1.1 and message 2.1). To provide the ATM with the *two* balances of the user's Account (as requested by messages 1 and 2), the BankDatabase must pass a `getAvailableBalance` and a `getTotalBalance` message to the user's Account. Such messages passed within the handling of another message are called **nested messages**. The UML recommends using a decimal numbering scheme to indicate nested messages. For example, message 1.1 is the first message nested in message 1—the BankDatabase passes a `getAvailableBalance` message during BankDatabase's processing of a message by the same name. [Note: If the BankDatabase needed to pass a second nested message while processing message 1, the second message would be numbered 1.2.] A message may be passed only when *all* the nested messages from the previous message have been passed. For example, the `BalanceInquiry` passes message 3 only after messages 2 and 2.1 have been passed, in that order.

The nested numbering scheme used in communication diagrams helps clarify precisely when and in what context each message is passed. For example, if we numbered the messages in Fig. 12.24 using a flat numbering scheme (i.e., 1, 2, 3, 4, 5), someone looking at the diagram might not be able to determine that BankDatabase passes the `getAvailableBalance` message (message 1.1) to an Account *during* the BankDatabase's processing of message 1, as opposed to *after* completing the processing of message 1. The nested decimal numbers make it clear that the second `getAvailableBalance` message (message 1.1) is passed to an Account within the handling of the first `getAvailableBalance` message (message 1) by the BankDatabase.

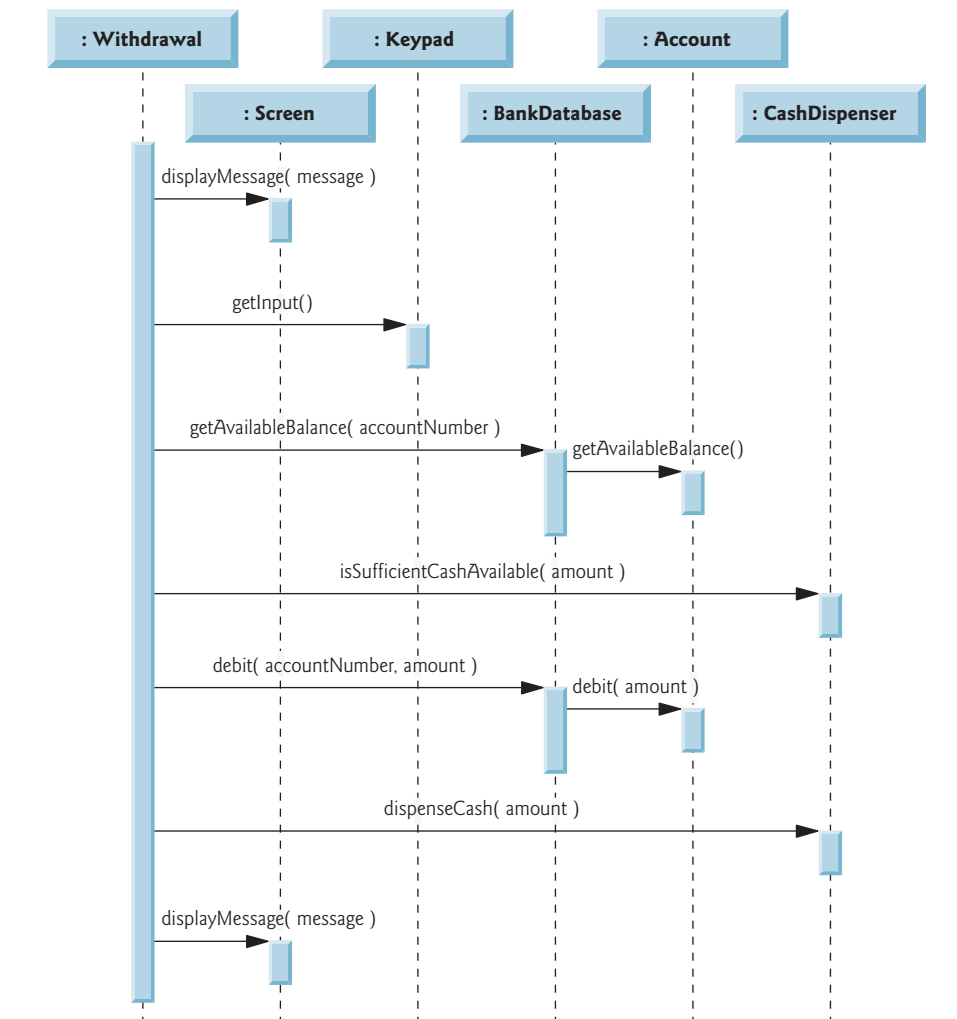

### Sequence Diagrams

Communication diagrams emphasize the participants in collaborations, but model their timing a bit awkwardly. A sequence diagram helps model the timing of collaborations more clearly. Figure 12.25 shows a sequence diagram modeling the sequence of interactions that occur when a `Withdrawal` executes. The dotted line extending down from an object's rectangle is that object's **lifeline**, which represents the progression of time. Actions occur along an object's lifeline in chronological order from top to bottom—an action near the top happens before one near the bottom.

Message passing in sequence diagrams is similar to message passing in communication diagrams. A solid arrow with a filled arrowhead extending from the sending object to the receiving object represents a message between two objects. The arrowhead points to an activation on the receiving object's lifeline. An **activation**, shown as a thin vertical rectangle, indicates that an object is executing. When an object returns control, a return message, represented as a dashed line with a stick ( $\Rightarrow$ ) arrowhead, extends from the activation of the object returning control to the activation of the object that initially sent the message. To eliminate clutter, we omit the return-message arrows—the UML allows this practice to make diagrams more readable. Like communication diagrams, sequence diagrams can indicate message parameters between the parentheses following a message name.

The sequence of messages in Fig. 12.25 begins when a `Withdrawal` prompts the user to choose a withdrawal amount by sending a `displayMessage` message to the `Screen`. The `Withdrawal` then sends a `getInput` message to the `Keypad`, which obtains input from the user. We've already modeled the control logic involved in a `Withdrawal` in the activity diagram of Fig. 12.15, so we do not show this logic in the sequence diagram of Fig. 12.25. Instead, we model the best-case scenario in which the balance of the user's account is

**Fig. 12.25** | Sequence diagram that models a `Withdrawal` executing.

greater than or equal to the chosen withdrawal amount, and the cash dispenser contains a sufficient amount of cash to satisfy the request. You can model control logic in a sequence diagram with UML frames (which are not covered in this case study). For a quick overview of UML frames, visit [www.agilemodeling.com/style/frame.htm](http://www.agilemodeling.com/style/frame.htm).

After obtaining a withdrawal amount, the `Withdrawal` sends a `getAvailableBalance` message to the `BankDatabase`, which in turn sends a `getAvailableBalance` message to the user's `Account`. Assuming that the user's account has enough money available to permit the transaction, the `Withdrawal` next sends an `isSufficientCashAvailable` message to the `CashDispenser`. Assuming that there's enough cash available, the `Withdrawal` decreases the balance of the user's account (i.e., both the `totalBalance` and the `availableBalance`) by sending a `debit` message to the `BankDatabase`. The `BankDatabase` responds by sending a `debit` message to the user's `Account`. Finally, the `Withdrawal` sends

a `dispenseCash` message to the `CashDispenser` and a `displayMessage` message to the `Screen`, telling the user to remove the cash from the machine.

We've identified the collaborations among objects in the ATM system and modeled some of them using UML interaction diagrams—both communication diagrams and sequence diagrams. In Section 13.2, we enhance the structure of our model to complete a preliminary object-oriented design, then we begin implementing the ATM system in Java.

## Self-Review Exercises for Section 12.7

**12.17** A(n) \_\_\_\_\_ consists of an object of one class sending a message to an object of another class.

- |                  |                |
|------------------|----------------|
| a) association   | b) aggregation |
| c) collaboration | d) composition |

**12.18** Which form of interaction diagram emphasizes *what* collaborations occur? Which form emphasizes *when* collaborations occur?

**12.19** Create a sequence diagram that models the interactions among objects in the ATM system that occur when a `Deposit` executes successfully, and explain the sequence of messages modeled by the diagram.

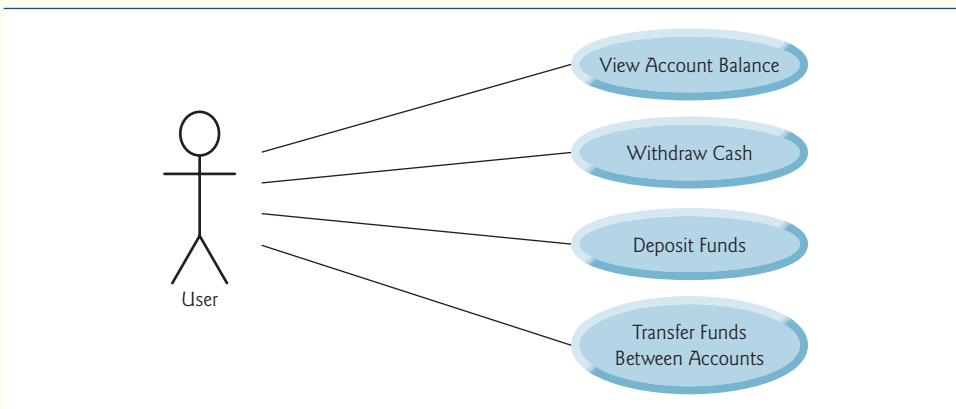

## 12.8 Wrap-Up

In this chapter, you learned how to work from a detailed requirements document to develop an object-oriented design. You worked with six popular types of UML diagrams to graphically model an object-oriented automated teller machine software system. In Chapter 13, we tune the design using inheritance, then completely implement the design in a 673-line Java application.

## Answers to Self-Review Exercises

**12.1** Figure 12.26 contains a use case diagram for a modified version of our ATM system that also allows users to transfer money between accounts.

**12.2** b.

**Fig. 12.26** | Use case diagram for a modified version of our ATM system that also allows users to transfer money between accounts.

12.3 d.

12.4 [Note: Student answers may vary.] Figure 12.27 presents a class diagram that shows some of the composition relationships of a class Car.

12.5 c. [Note: In a computer network, this relationship could be many-to-many.]

12.6 True.

12.7 Figure 12.28 presents a class diagram for the ATM including class Deposit instead of class Withdrawal (as in Fig. 12.10). Deposit does not access CashDispenser, but does access DepositSlot.

Fig. 12.27 | Class diagram showing composition relationships of a class Car.

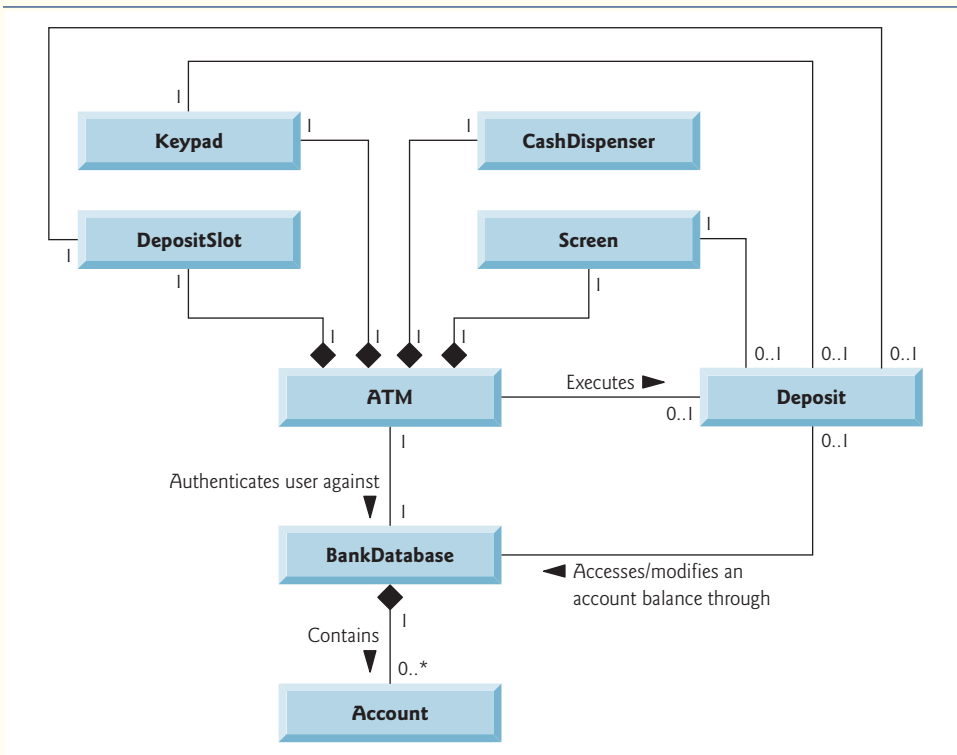

Fig. 12.28 | Class diagram for the ATM system model including class Deposit.

**12.8** b.

**12.9** c. Fly is an operation or behavior of an airplane, not an attribute.

**12.10** This indicates that count is an Integer with an initial value of 500. This attribute keeps track of the number of bills available in the CashDispenser at any given time.

**12.11** False. State diagrams model some of the behavior of a system.

**12.12** a.

**12.13** Figure 12.29 models the actions that occur after the user chooses the deposit option from the main menu and before the ATM returns the user to the main menu. Recall that part of receiving a deposit amount from the user involves converting an integer number of cents to a dollar amount. Also recall that crediting a deposit amount to an account increases only the totalBalance attribute of the user's Account object. The bank updates the availableBalance attribute of the user's Account object only after confirming the amount of cash in the deposit envelope and after the enclosed checks clear—this occurs independently of the ATM system.

**Fig. 12.29** | Activity diagram for a deposit transaction.

12.14 c.

12.15 To specify an operation that retrieves the amount attribute of class `Withdrawal`, the following operation listing would be placed in the operation (i.e., third) compartment of class `Withdrawal`:

```
getAmount( ) : Double
```

12.16 This operation listing indicates an operation named `add` that takes integers `x` and `y` as parameters and returns an integer value.

12.17 c.

12.18 Communication diagrams emphasize *what* collaborations occur. Sequence diagrams emphasize *when* collaborations occur.

12.19 Figure 12.30 presents a sequence diagram that models the interactions between objects in the ATM system that occur when a `Deposit` executes successfully. A `Deposit` first sends a `displayMessage` message to the `Screen` to ask the user to enter a deposit amount. Next the `Deposit` sends a `getInput` message to the `Keypad` to receive input from the user. The `Deposit` then instructs the user to enter a deposit envelope by sending a `displayMessage` message to the `Screen`. The `Deposit` next sends an `isEnvelopeReceived` message to the `DepositSlot` to confirm that the deposit envelope has been received by the ATM. Finally, the `Deposit` increases the `totalBalance` attribute (but not the `availableBalance` attribute) of the user's `Account` by sending a `credit` message to the `BankDatabase`. The `BankDatabase` responds by sending the same message to the user's `Account`.

Fig. 12.30 | Sequence diagram that models a `Deposit` executing.

## ATM Case Study Part 2: Implementing an Object- Oriented Design

*You can't work in the abstract.*  
—I. M. Pei

*To generalize means to think.*  
—Georg Wilhelm Friedrich Hegel

*We are all gifted. That is our inheritance.*  
—Ethel Waters

*Let me walk through the fields  
of paper  
touching with my wand  
dry stems and stunted  
butterflies...*  
—Denise Levertov

### Objectives

In this chapter you'll:

- Incorporate inheritance into the design of the ATM.
- Incorporate polymorphism into the design of the ATM.
- Fully implement in Java the UML-based object-oriented design of the ATM software.
- Study a detailed code walkthrough of the ATM software system that explains the implementation issues.

- |                                                                                                                                                                                                                                                                                                                                                                                                                                  |                                                                                                                                                                                                                                                                                                                                                                                          |

*Answers to Self-Review Exercises*

## 13.1 Introduction

In Chapter 12, we developed an object-oriented design for our ATM system. We now implement our object-oriented design in Java. In Section 13.2, we show how to convert class diagrams to Java code. In Section 13.3, we tune the design with inheritance and polymorphism. Then we present a full Java code implementation of the ATM software in Section 13.4. The code is carefully commented and the discussions of the implementation are thorough and precise. Studying this application provides the opportunity for you to see a more substantial application of the kind you're likely to encounter in industry.

## 13.2 Starting to Program the Classes of the ATM System

[*Note:* This section can be taught after Chapter 8.]

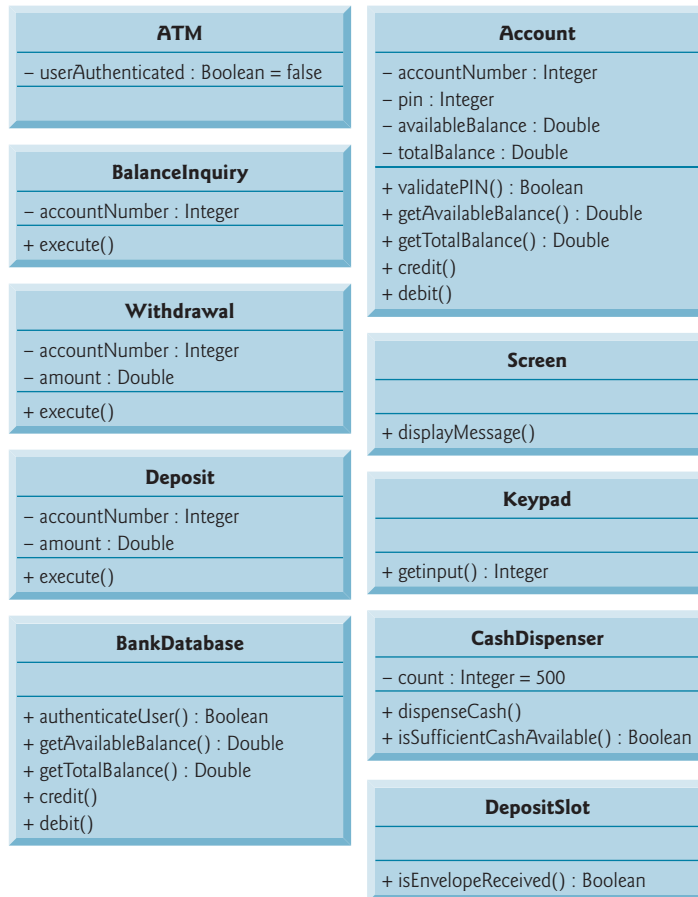

### *Visibility*

We now apply access modifiers to the members of our classes. We've introduced access modifiers `public` and `private`. Access modifiers determine the **visibility** or accessibility of an object's attributes and methods to other objects. Before we can begin implementing our design, we must consider which attributes and methods of our classes should be `public` and which should be `private`.

We've observed that attributes normally should be `private` and that methods invoked by clients of a given class should be `public`. Methods that are called as "utility methods" only by other methods of the same class normally should be `private`. The UML employs **visibility markers** for modeling the visibility of attributes and operations. Public visibility is indicated by placing a plus sign (+) before an operation or an attribute, whereas a minus sign (−) indicates private visibility. Figure 13.1 shows our updated class diagram with visibility markers included. [*Note:* We do not include any operation parameters in Fig. 13.1—this is perfectly normal. Adding visibility markers does not affect the parameters already modeled in the class diagrams of Figs. 12.17–12.21.]

### *Navigability*

Before we begin implementing our design in Java, we introduce an additional UML notation. The class diagram in Fig. 13.2 further refines the relationships among classes in the ATM system by adding navigability arrows to the association lines. **Navigability arrows** (represented as arrows with stick ( $\Rightarrow$ ) arrowheads in the class diagram) indicate in the

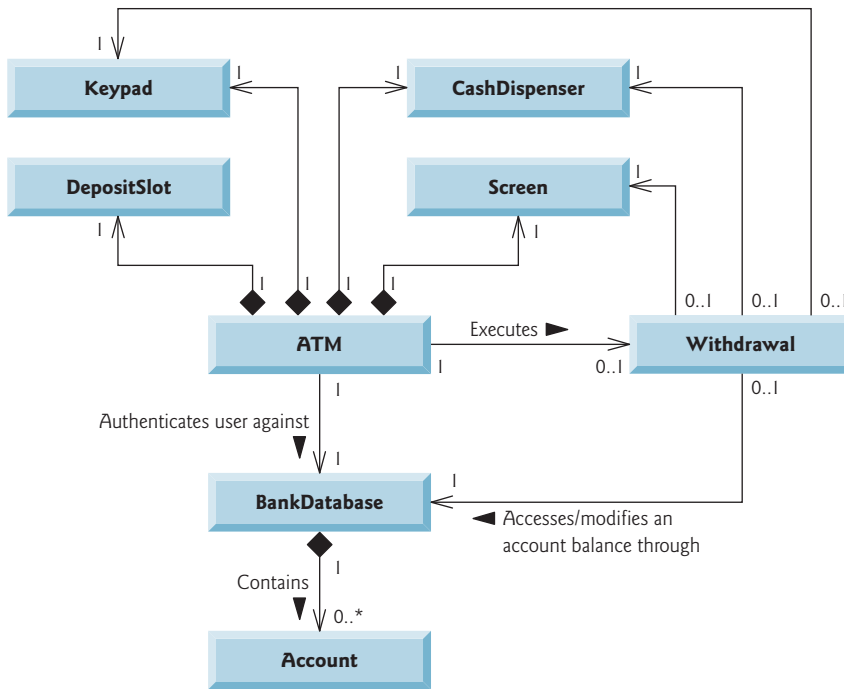

**Fig. 13.1** | Class diagram with visibility markers.

direction which an association can be traversed. When implementing a system designed using the UML, you use navigability arrows to determine which objects need references to other objects. For example, the navigability arrow pointing from class ATM to class BankDatabase indicates that we can navigate from the former to the latter, thereby enabling the ATM to invoke the BankDatabase's operations. However, since Fig. 13.2 does *not* contain a navigability arrow pointing from class BankDatabase to class ATM, the BankDatabase cannot access the ATM's operations. Associations in a class diagram that have navigability arrows at both ends or have none at all indicate **bidirectional navigability**—navigation can proceed in either direction across the association.

Like the class diagram of Fig. 12.10, that of Fig. 13.2 omits classes BalanceInquiry and Deposit for simplicity. The navigability of the associations in which these classes participate closely parallels that of class Withdrawal. Recall from Section 12.3 that BalanceInquiry has an association with class Screen. We can navigate from class BalanceInquiry to class Screen along this association, but we cannot navigate from class Screen to class BalanceInquiry. Thus, if we were to model class BalanceInquiry in Fig. 13.2, we would place a navigability

**Fig. 13.2** | Class diagram with navigability arrows.

arrow at class `Screen`'s end of this association. Also recall that class `Deposit` associates with classes `Screen`, `Keypad` and `DepositSlot`. We can navigate from class `Deposit` to each of these classes, but *not* vice versa. We therefore would place navigability arrows at the `Screen`, `Keypad` and `DepositSlot` ends of these associations. [Note: We model these additional classes and associations in our final class diagram in Section 13.3, after we've simplified the structure of our system by incorporating the object-oriented concept of inheritance.]

### Implementing the ATM System from Its UML Design

We're now ready to begin implementing the ATM system. We first convert the classes in the diagrams of Fig. 13.1 and Fig. 13.2 into Java code. The code will represent the "skeleton" of the system. In Section 13.3, we modify the code to incorporate inheritance. In Section 13.4, we present the complete working Java code for our model.

As an example, we develop the code from our design of class `Withdrawal` in Fig. 13.1. We use this figure to determine the attributes and operations of the class. We use the UML model in Fig. 13.2 to determine the associations among classes. We follow the following four guidelines for each class:

1. Use the name located in the first compartment to declare the class as a `public` class with an empty no-argument constructor. We include this constructor simply as a placeholder to remind us that *most classes will indeed need custom constructors*. In Section 13.4, when we complete a working version of this class, we'll add arguments and code the body of the constructor as needed. For example, class

Withdrawal yields the code in Fig. 13.3. If we find that the class's instance variables require only default initialization, then we'll remove the empty no-argument constructor because it's unnecessary.

---

```

1 // Class Withdrawal represents an ATM withdrawal transaction
2 public class Withdrawal
3 {
4     // no-argument constructor
5     public Withdrawal()
6     {
7     } // end no-argument Withdrawal constructor
8 } // end class Withdrawal

```

---

**Fig. 13.3** | Java code for class Withdrawal based on Figs. 13.1–13.2.

2. Use the attributes located in the second compartment to declare the instance variables. For example, the private attributes `accountNumber` and `amount` of class `Withdrawal` yield the code in Fig. 13.4. [*Note:* The constructor of the complete working version of this class will assign values to these attributes.]

---

```

1 // Class Withdrawal represents an ATM withdrawal transaction
2 public class Withdrawal
3 {
4     // attributes
5     private int accountNumber; // account to withdraw funds from
6     private double amount; // amount to withdraw
7
8     // no-argument constructor
9     public Withdrawal()
10    {
11    } // end no-argument Withdrawal constructor
12 } // end class Withdrawal

```

---

**Fig. 13.4** | Java code for class Withdrawal based on Figs. 13.1–13.2.

3. Use the associations described in the class diagram to declare the references to other objects. For example, according to Fig. 13.2, `Withdrawal` can access one object of class `Screen`, one object of class `Keypad`, one object of class `CashDispenser` and one object of class `BankDatabase`. This yields the code in Fig. 13.5. [*Note:* The constructor of the complete working version of this class will initialize these instance variables with references to actual objects.]
4. Use the operations located in the third compartment of Fig. 13.1 to declare the shells of the methods. If we have not yet specified a return type for an operation, we declare the method with return type `void`. Refer to the class diagrams of Figs. 12.17–12.21 to declare any necessary parameters. For example, adding the public operation `execute` in class `Withdrawal`, which has an empty parameter list, yields the code in Fig. 13.6. [*Note:* We code the bodies of methods when we implement the complete system in Section 13.4.]

This concludes our discussion of the basics of generating classes from UML diagrams.

---

```

1 // Class Withdrawal represents an ATM withdrawal transaction
2 public class Withdrawal
3 {
4     // attributes
5     private int accountNumber; // account to withdraw funds from
6     private double amount; // amount to withdraw
7
8     // references to associated objects
9     private Screen screen; // ATM's screen
10    private Keypad keypad; // ATM's keypad
11    private CashDispenser cashDispenser; // ATM's cash dispenser
12    private BankDatabase bankDatabase; // account info database
13
14    // no-argument constructor
15    public Withdrawal()
16    {
17    } // end no-argument Withdrawal constructor
18 } // end class Withdrawal

```

---

**Fig. 13.5** | Java code for class `Withdrawal` based on Figs. 13.1–13.2.

---

```

1 // Class Withdrawal represents an ATM withdrawal transaction
2 public class Withdrawal
3 {
4     // attributes
5     private int accountNumber; // account to withdraw funds from
6     private double amount; // amount to withdraw
7
8     // references to associated objects
9     private Screen screen; // ATM's screen
10    private Keypad keypad; // ATM's keypad
11    private CashDispenser cashDispenser; // ATM's cash dispenser
12    private BankDatabase bankDatabase; // account info database
13
14    // no-argument constructor
15    public Withdrawal()
16    {
17    } // end no-argument Withdrawal constructor
18
19    // operations
20    public void execute()
21    {
22    } // end method execute
23 } // end class Withdrawal

```

---

**Fig. 13.6** | Java code for class `Withdrawal` based on Figs. 13.1–13.2.

## Self-Review Exercises for Section 13.2

**13.1** State whether the following statement is *true* or *false*, and if *false*, explain why: If an attribute of a class is marked with a minus sign (-) in a class diagram, the attribute is not directly accessible outside the class.

**13.2** In Fig. 13.2, the association between the ATM and the Screen indicates that:

- we can navigate from the Screen to the ATM
- we can navigate from the ATM to the Screen
- Both (a) and (b); the association is bidirectional
- None of the above

**13.3** Write Java code to begin implementing the design for class Keypad.

## 13.3 Incorporating Inheritance and Polymorphism into the ATM System

[*Note: This section can be taught after Chapter 10.*]

We now revisit our ATM system design to see how it might benefit from inheritance. To apply inheritance, we first look for *commonality among classes* in the system. We create an inheritance hierarchy to model similar (yet not identical) classes in a more elegant and efficient manner. We then modify our class diagram to incorporate the new inheritance relationships. Finally, we demonstrate how our updated design is translated into Java code.

In Section 12.3, we encountered the problem of representing a financial transaction in the system. Rather than create one class to represent all transaction types, we decided to create three individual transaction classes—`BalanceInquiry`, `Withdrawal` and `Deposit`—to represent the transactions that the ATM system can perform. Figure 13.7 shows the attributes and operations of classes `BalanceInquiry`, `Withdrawal` and `Deposit`. These classes have one attribute (`accountNumber`) and one operation (`execute`) in common. Each class requires attribute `accountNumber` to specify the account to which the transaction applies. Each class contains operation `execute`, which the ATM invokes to perform the transaction. Clearly, `BalanceInquiry`, `Withdrawal` and `Deposit` represent *types of* transactions. Figure 13.7 reveals commonality among the transaction classes, so using inheritance to factor out the common features seems appropriate for designing classes `BalanceInquiry`, `Withdrawal` and `Deposit`. We place the common functionality in a superclass, `Transaction`, that classes `BalanceInquiry`, `Withdrawal` and `Deposit` extend.

**Fig. 13.7** | Attributes and operations of `BalanceInquiry`, `Withdrawal` and `Deposit`.

### Generalization

The UML specifies a relationship called a **generalization** to model inheritance. Figure 13.8 is the class diagram that models the generalization of superclass `Transaction` and subclasses `BalanceInquiry`, `Withdrawal` and `Deposit`. The arrows with triangular

hollow arrowheads indicate that classes `BalanceInquiry`, `Withdrawal` and `Deposit` extend class `Transaction`. Class `Transaction` is said to be a generalization of classes `BalanceInquiry`, `Withdrawal` and `Deposit`. Class `BalanceInquiry`, `Withdrawal` and `Deposit` are said to be **specializations** of class `Transaction`.

**Fig. 13.8** | Class diagram modeling generalization of superclass `Transaction` and subclasses `BalanceInquiry`, `Withdrawal` and `Deposit`. Abstract class names (e.g., `Transaction`) and method names (e.g., `execute` in class `Transaction`) appear in italics.

Classes `BalanceInquiry`, `Withdrawal` and `Deposit` share integer attribute `accountNumber`, so we *factor out* this *common attribute* and place it in superclass `Transaction`. We no longer list `accountNumber` in the second compartment of each subclass, because the three subclasses *inherit* this attribute from `Transaction`. Recall, however, that subclasses cannot directly access private attributes of a superclass. We therefore include public method `getAccountNumber` in class `Transaction`. Each subclass will inherit this method, enabling the subclass to access its `accountNumber` as needed to execute a transaction.

According to Fig. 13.7, classes `BalanceInquiry`, `Withdrawal` and `Deposit` also share operation `execute`, so we placed public method `execute` in superclass `Transaction`. However, it does *not* make sense to implement `execute` in class `Transaction`, because the functionality that this method provides *depends on the type of the actual transaction*. We therefore declare method `execute` as abstract in superclass `Transaction`. Any class that contains at least one abstract method must also be declared abstract. This forces any subclass of `Transaction` that must be a *concrete* class (i.e., `BalanceInquiry`, `Withdrawal` and `Deposit`) to implement method `execute`. The UML requires that we place abstract class names (and abstract methods) in italics, so `Transaction` and its method `execute` appear in italics in Fig. 13.8. Method `execute` is *not* italicized in subclasses `BalanceInquiry`, `Withdrawal` and `Deposit`. Each subclass overrides superclass `Transaction`'s `execute` method with a concrete implementation that performs the steps appropriate for completing that type of transaction. Figure 13.8 includes operation `execute` in the third compartment of classes `BalanceInquiry`, `Withdrawal` and `Deposit`, because each class has a different concrete implementation of the overridden method.

### *Processing Transactions Polymorphically*

Polymorphism provides the ATM with an elegant way to execute all transactions “in the general.” For example, suppose a user chooses to perform a balance inquiry. The ATM sets a

Transaction reference to a new `BalanceInquiry` object. When the ATM uses its `Transaction` reference to invoke method `execute`, `BalanceInquiry`'s version of `execute` is called.

This *polymorphic* approach also makes the system easily *extensible*. Should we wish to create a new transaction type (e.g., funds transfer or bill payment), we would just create an additional `Transaction` subclass that overrides the `execute` method with a version of the method appropriate for executing the new transaction type. We would need to make only minimal changes to the system code to allow users to choose the new transaction type from the main menu and for the ATM to instantiate and execute objects of the new subclass. The ATM could execute transactions of the new type using the current code, because it executes all transactions *polymorphically* using a general `Transaction` reference.

Recall that an abstract class like `Transaction` is one for which you never intend to instantiate objects. An abstract class simply declares common attributes and behaviors of its subclasses in an inheritance hierarchy. Class `Transaction` defines the concept of what it means to be a transaction that has an account number and executes. You may wonder why we bother to include abstract method `execute` in class `Transaction` if it lacks a concrete implementation. Conceptually, we include it because it corresponds to the defining behavior of *all* transactions—executing. Technically, we must include method `execute` in superclass `Transaction` so that the ATM (or any other class) can polymorphically invoke each subclass's *overridden* version of this method through a `Transaction` reference. Also, from a software engineering perspective, including an abstract method in a superclass forces the implementor of the subclasses to override that method with concrete implementations in the subclasses, or else the subclasses, too, will be abstract, preventing objects of those subclasses from being instantiated.

### *Additional Attribute of Classes `Withdrawal` and `Deposit`*

Subclasses `BalanceInquiry`, `Withdrawal` and `Deposit` inherit attribute `accountNumber` from superclass `Transaction`, but classes `Withdrawal` and `Deposit` contain the additional attribute `amount` that distinguishes them from class `BalanceInquiry`. Classes `Withdrawal` and `Deposit` require this additional attribute to store the amount of money that the user wishes to withdraw or deposit. Class `BalanceInquiry` has no need for such an attribute and requires only an account number to execute. Even though two of the three `Transaction` subclasses share this attribute, we do *not* place it in superclass `Transaction`—we place only features *common* to all the subclasses in the superclass, otherwise subclasses could inherit attributes (and methods) that they do not need and should not have.

### *Class Diagram with `Transaction` Hierarchy Incorporated*

Figure 13.9 presents an updated class diagram of our model that incorporates inheritance and introduces class `Transaction`. We model an association between class `ATM` and class `Transaction` to show that the ATM, at any given moment, either is executing a transaction or is not (i.e., zero or one objects of type `Transaction` exist in the system at a time). Because a `Withdrawal` is a type of `Transaction`, we no longer draw an association line directly between class `ATM` and class `Withdrawal`. Subclass `Withdrawal` inherits superclass `Transaction`'s association with class `ATM`. Subclasses `BalanceInquiry` and `Deposit` inherit this association, too, so the previously omitted associations between `ATM` and classes `BalanceInquiry` and `Deposit` no longer exist either.

**Fig. 13.9** | Class diagram of the ATM system (incorporating inheritance). The abstract class name *Transaction* appears in italics.

We also add an association between class *Transaction* and the *BankDatabase* (Fig. 13.9). All *Transactions* require a reference to the *BankDatabase* so they can access and modify account information. Because each *Transaction* subclass inherits this reference, we no longer model the association between class *Withdrawal* and the *BankDatabase*. Similarly, the previously omitted associations between the *BankDatabase* and classes *BalanceInquiry* and *Deposit* no longer exist.

We show an association between class *Transaction* and the *Screen*. All *Transactions* display output to the user via the *Screen*. Thus, we no longer include the association previously modeled between *Withdrawal* and the *Screen*, although *Withdrawal* still participates in associations with the *CashDispenser* and the *Keypad*. Our class diagram incorporating inheritance also models *Deposit* and *BalanceInquiry*. We show associations between *Deposit* and both the *DepositSlot* and the *Keypad*. Class *BalanceInquiry* takes part in no associations other than those inherited from class *Transaction*—a *BalanceInquiry* needs to interact only with the *BankDatabase* and with the *Screen*.

Figure 13.1 showed attributes and operations with visibility markers. Now in Fig. 13.10 we present a modified class diagram that incorporates inheritance. This abbreviated diagram does not show inheritance relationships, but instead shows the attributes and methods after we've employed inheritance in our system. To save space, as we did in

Fig. 12.12, we do not include those attributes shown by associations in Fig. 13.9—we do, however, include them in the Java implementation in Section 13.4. We also omit all operation parameters, as we did in Fig. 13.1—incorporating inheritance does not affect the parameters already modeled in Figs. 12.17–12.21.

**Software Engineering Observation 13.1**

*A complete class diagram shows all the associations among classes and all the attributes and operations for each class. When the number of class attributes, methods and associations is substantial (as in Figs. 13.9 and 13.10), a good practice that promotes readability is to divide this information between two class diagrams—one focusing on associations and the other on attributes and methods.*

**Fig. 13.10** | Class diagram with attributes and operations (incorporating inheritance). The abstract class name *Transaction* and the abstract method name *execute* in class *Transaction* appear in italics.

*Implementing the ATM System Design (Incorporating Inheritance)*

In Section 13.2, we began implementing the ATM system design in Java code. We now modify our implementation to incorporate inheritance, using class `Withdrawal` as an example.

1. If a class A is a generalization of class B, then class B extends class A in the class declaration. For example, abstract superclass `Transaction` is a generalization of class `Withdrawal`. Figure 13.11 shows the declaration of class `Withdrawal`.

---

```

1 // Class Withdrawal represents an ATM withdrawal transaction
2 public class Withdrawal extends Transaction
3 {
4 } // end class Withdrawal

```

---

**Fig. 13.11** | Java code for shell of class `Withdrawal`.

2. If class A is an abstract class and class B is a subclass of class A, then class B must implement the *abstract* methods of class A if class B is to be a *concrete* class. For example, class `Transaction` contains abstract method `execute`, so class `Withdrawal` must implement this method if we want to instantiate a `Withdrawal` object. Figure 13.12 is the Java code for class `Withdrawal` from Fig. 13.9 and Fig. 13.10. Class `Withdrawal` inherits field `accountNumber` from superclass `Transaction`, so `Withdrawal` does not need to declare this field. Class `Withdrawal` also inherits references to the `Screen` and the `BankDatabase` from its superclass `Transaction`, so we do not include these references in our code. Figure 13.10 specifies attribute `amount` and operation `execute` for class `Withdrawal`. Line 6 of Fig. 13.12 declares a field for attribute `amount`. Lines 16–19 declare the shell of a method for operation `execute`. Recall that subclass `Withdrawal` must provide a concrete implementation of the abstract method `execute` in superclass `Transaction`. The keypad and `cashDispenser` references (lines 7–8) are fields derived from `Withdrawal`'s associations in Fig. 13.9. The constructor in the complete working version of this class will initialize these references to actual objects.

---

```

1 // Withdrawal.java
2 // Generated using the class diagrams in Fig. 13.9 and Fig. 13.10
3 public class Withdrawal extends Transaction
4 {
5     // attributes
6     private double amount; // amount to withdraw
7     private Keypad keypad; // reference to keypad
8     private CashDispenser cashDispenser; // reference to cash dispenser
9
10    // no-argument constructor
11    public Withdrawal()
12    {
13    } // end no-argument Withdrawal constructor
14

```

---

**Fig. 13.12** | Java code for class `Withdrawal` based on Figs. 13.9 and 13.10. (Part I of 2.)

```

15 // method overriding execute
16 @Override
17 public void execute()
18 {
19 } // end method execute
20 } // end class Withdrawal

```

### Software Engineering Observation 13.2

Several UML modeling tools can convert UML-based designs into Java code, speeding the implementation process considerably. For more information on these tools, visit our UML Resource Center at [www.deitel.com/UML/](http://www.deitel.com/UML/).

Congratulations on completing the case study's design portion! We implement the ATM system in Java code in Section 13.4. We recommend that you carefully read the code and its description. The code is abundantly commented and precisely follows the design with which you're now familiar. The accompanying description is carefully written to guide your understanding of the implementation based on the UML design. Mastering this code is a wonderful culminating accomplishment after studying Sections 12.2–12.7 and 13.2–13.3.

## Self-Review Exercises for Section 13.3

- 13.4** The UML uses an arrow with a \_\_\_\_\_ to indicate a generalization relationship.
- solid filled arrowhead
  - triangular hollow arrowhead
  - diamond-shaped hollow arrowhead
  - stick arrowhead
- 13.5** State whether the following statement is *true* or *false*, and if *false*, explain why: The UML requires that we underline abstract class names and method names.
- 13.6** Write Java code to begin implementing the design for class `Transaction` specified in Figs. 13.9 and 13.10. Be sure to include private reference-type attributes based on class `Transaction`'s associations. Also be sure to include public *get* methods that provide access to any of these private attributes that the subclasses require to perform their tasks.

## 13.4 ATM Case Study Implementation

This section contains the complete working 673-line implementation of the ATM system. We consider the classes in the order in which we identified them in Section 12.3—`ATM`, `Screen`, `Keypad`, `CashDispenser`, `DepositSlot`, `Account`, `BankDatabase`, `Transaction`, `BalanceInquiry`, `Withdrawal` and `Deposit`.

We apply the guidelines discussed in Sections 13.2–13.3 to code these classes based on how we modeled them in the UML class diagrams of Figs. 13.9 and 13.10. To develop the bodies of class methods, we refer to the activity diagrams in Section 12.5 and the communication and sequence diagrams presented in Section 12.7. Our ATM design does *not* specify all the program logic and may not specify all the attributes and operations required to complete the ATM implementation. This is a *normal* part of the object-oriented design

process. As we implement the system, we complete the program logic and add attributes and behaviors as necessary to construct the ATM system specified by the requirements document in Section 12.2.

We conclude the discussion by presenting a Java application (`ATMCaseStudy`) that starts the ATM and puts the other classes in the system in use. Recall that we're developing a first version of the ATM system that runs on a personal computer and uses the computer's keyboard and monitor to approximate the ATM's keypad and screen. We also simulate only the actions of the ATM's cash dispenser and deposit slot. We attempt to implement the system, however, so that real hardware versions of these devices could be integrated without significant changes in the code.

### 13.4.1 Class ATM

Class `ATM` (Fig. 13.13) represents the ATM as a whole. Lines 6–12 implement the class's attributes. We determine all but one of these attributes from the UML class diagrams of Figs. 13.9 and 13.10. We implement the UML `Boolean` attribute `userAuthenticated` in Fig. 13.10 as a `boolean` in Java (line 6). Line 7 declares an attribute not found in our UML design—an `int` attribute `currentAccountNumber` that keeps track of the account number of the current authenticated user. We'll soon see how the class uses this attribute. Lines 8–12 declare reference-type attributes corresponding to the ATM class's associations modeled in the class diagram of Fig. 13.9. These attributes allow the ATM to access its parts (i.e., its `Screen`, `Keypad`, `CashDispenser` and `DepositSlot`) and interact with the bank's account-information database (i.e., a `BankDatabase` object).

---

```

1 // ATM.java
2 // Represents an automated teller machine
3
4 public class ATM
5 {
6     private boolean userAuthenticated; // whether user is authenticated
7     private int currentAccountNumber; // current user's account number
8     private Screen screen; // ATM's screen
9     private Keypad keypad; // ATM's keypad
10    private CashDispenser cashDispenser; // ATM's cash dispenser
11    private DepositSlot depositSlot; // ATM's deposit slot
12    private BankDatabase bankDatabase; // account information database
13
14    // constants corresponding to main menu options
15    private static final int BALANCE_INQUIRY = 1;
16    private static final int WITHDRAWAL = 2;
17    private static final int DEPOSIT = 3;
18    private static final int EXIT = 4;
19
20    // no-argument ATM constructor initializes instance variables
21    public ATM()
22    {
23        userAuthenticated = false; // user is not authenticated to start
24        currentAccountNumber = 0; // no current account number to start
25        screen = new Screen(); // create screen

```

---

**Fig. 13.13** | Class `ATM` represents the ATM. (Part I of 4.)

```

26     keypad = new Keypad(); // create keypad
27     cashDispenser = new CashDispenser(); // create cash dispenser
28     depositSlot = new DepositSlot(); // create deposit slot
29     bankDatabase = new BankDatabase(); // create acct info database
30 } // end no-argument ATM constructor
31
32 // start ATM
33 public void run()
34 {
35     // welcome and authenticate user; perform transactions
36     while ( true )
37     {
38         // loop while user is not yet authenticated
39         while ( !userAuthenticated )
40         {
41             screen.displayMessageLine( "\nWelcome!" );
42             authenticateUser(); // authenticate user
43         } // end while
44
45         performTransactions(); // user is now authenticated
46         userAuthenticated = false; // reset before next ATM session
47         currentAccountNumber = 0; // reset before next ATM session
48         screen.displayMessageLine( "\nThank you! Goodbye!" );
49     } // end while
50 } // end method run
51
52 // attempts to authenticate user against database
53 private void authenticateUser()
54 {
55     screen.displayMessage( "\nPlease enter your account number: " );
56     int accountNumber = keypad.getInput(); // input account number
57     screen.displayMessage( "\nEnter your PIN: " ); // prompt for PIN
58     int pin = keypad.getInput(); // input PIN
59
60     // set userAuthenticated to boolean value returned by database
61     userAuthenticated =
62         bankDatabase.authenticateUser( accountNumber, pin );
63
64     // check whether authentication succeeded
65     if ( userAuthenticated )
66     {
67         currentAccountNumber = accountNumber; // save user's account #
68     } // end if
69     else
70         screen.displayMessageLine(
71             "Invalid account number or PIN. Please try again." );
72 } // end method authenticateUser
73
74 // display the main menu and perform transactions
75 private void performTransactions()
76 {
77     // local variable to store transaction currently being processed
78     Transaction currentTransaction = null;

```

**Fig. 13.13** | Class ATM represents the ATM. (Part 2 of 4.)

```

79
80     boolean userExited = false; // user has not chosen to exit
81
82     // loop while user has not chosen option to exit system
83     while ( !userExited )
84     {
85         // show main menu and get user selection
86         int mainMenuSelection = displayMainMenu();
87
88         // decide how to proceed based on user's menu selection
89         switch ( mainMenuSelection )
90         {
91             // user chose to perform one of three transaction types
92             case BALANCE_INQUIRY:
93             case WITHDRAWAL:
94             case DEPOSIT:
95
96                 // initialize as new object of chosen type
97                 currentTransaction =
98                     createTransaction( mainMenuSelection );
99
100                currentTransaction.execute(); // execute transaction
101                break;
102            case EXIT: // user chose to terminate session
103                screen.displayMessageLine( "\nExiting the system..." );
104                userExited = true; // this ATM session should end
105                break;
106            default: // user did not enter an integer from 1-4
107                screen.displayMessageLine(
108                    "\nYou did not enter a valid selection. Try again." );
109                break;
110        } // end switch
111    } // end while
112 } // end method performTransactions
113
114 // display the main menu and return an input selection
115 private int displayMainMenu()
116 {
117     screen.displayMessageLine( "\nMain menu:" );
118     screen.displayMessageLine( "1 - View my balance" );
119     screen.displayMessageLine( "2 - Withdraw cash" );
120     screen.displayMessageLine( "3 - Deposit funds" );
121     screen.displayMessageLine( "4 - Exit\n" );
122     screen.displayMessage( "Enter a choice: " );
123     return keypad.getInput(); // return user's selection
124 } // end method displayMainMenu
125
126 // return object of specified Transaction subclass
127 private Transaction createTransaction( int type )
128 {
129     Transaction temp = null; // temporary Transaction variable
130

```

**Fig. 13.13** | Class ATM represents the ATM. (Part 3 of 4.)

```

131     // determine which type of Transaction to create
132     switch ( type )
133     {
134         case BALANCE_INQUIRY: // create new BalanceInquiry transaction
135             temp = new BalanceInquiry(
136                 currentAccountNumber, screen, bankDatabase );
137             break;
138         case WITHDRAWAL: // create new Withdrawal transaction
139             temp = new Withdrawal( currentAccountNumber, screen,
140                 bankDatabase, keypad, cashDispenser );
141             break;
142         case DEPOSIT: // create new Deposit transaction
143             temp = new Deposit( currentAccountNumber, screen,
144                 bankDatabase, keypad, depositSlot );
145             break;
146     } // end switch
147
148     return temp; // return the newly created object
149 } // end method createTransaction
150 } // end class ATM

```

**Fig. 13.13** | Class ATM represents the ATM. (Part 4 of 4.)

Lines 15–18 declare integer constants that correspond to the four options in the ATM’s main menu (i.e., balance inquiry, withdrawal, deposit and exit). Lines 21–30 declare the constructor, which initializes the class’s attributes. When an ATM object is first created, no user is authenticated, so line 23 initializes `userAuthenticated` to `false`. Likewise, line 24 initializes `currentAccountNumber` to 0 because there’s no current user yet. Lines 25–28 instantiate new objects to represent the ATM’s parts. Recall that class ATM has composition relationships with classes `Screen`, `Keypad`, `CashDispenser` and `DepositSlot`, so class ATM is responsible for their creation. Line 29 creates a new `BankDatabase`. [*Note:* If this were a real ATM system, the ATM class would receive a reference to an existing database object created by the bank. However, in this implementation we’re only simulating the bank’s database, so class ATM creates the `BankDatabase` object with which it interacts.]

### *ATM Method run*

The class diagram of Fig. 13.10 does not list any operations for class ATM. We now implement one operation (i.e., `public` method) in class ATM that allows an external client of the class (i.e., class `ATMCaseStudy`) to tell the ATM to run. ATM method `run` (lines 33–50) uses an infinite loop (lines 36–49) to repeatedly welcome a user, attempt to authenticate the user and, if authentication succeeds, allow the user to perform transactions. After an authenticated user performs the desired transactions and chooses to exit, the ATM resets itself, displays a goodbye message to the user and restarts the process. We use an infinite loop here to simulate the fact that an ATM appears to run continuously until the bank turns it off (an action beyond the user’s control). An ATM user has the option to exit the system but not the ability to turn off the ATM completely.

### *Authenticating a User*

In method `run`’s infinite loop, lines 39–43 cause the ATM to repeatedly welcome and attempt to authenticate the user as long as the user has not been authenticated (i.e., `!user-`

Authenticated is true). Line 41 invokes method `displayMessageLine` of the ATM's screen to display a welcome message. Like Screen method `displayMessage` designed in the case study, method `displayMessageLine` (declared in lines 13–16 of Fig. 13.14) displays a message to the user, but this method also outputs a newline after the message. We've added this method during implementation to give class Screen's clients more control over the placement of displayed messages. Line 42 invokes class ATM's private utility method `authenticateUser` (declared in lines 53–72) to attempt to authenticate the user.

We refer to the requirements document to determine the steps necessary to authenticate the user before allowing transactions to occur. Line 55 of method `authenticateUser` invokes method `displayMessage` of the screen to prompt the user to enter an account number. Line 56 invokes method `getInput` of the keypad to obtain the user's input, then stores the integer value entered by the user in a local variable `accountNumber`. Method `authenticateUser` next prompts the user to enter a PIN (line 57), and stores the PIN input by the user in a local variable `pin` (line 58). Next, lines 61–62 attempt to authenticate the user by passing the `accountNumber` and `pin` entered by the user to the `bankDatabase`'s `authenticateUser` method. Class ATM sets its `userAuthenticated` attribute to the `boolean` value returned by this method—`userAuthenticated` becomes `true` if authentication succeeds (i.e., `accountNumber` and `pin` match those of an existing `Account` in `bankDatabase`) and remains `false` otherwise. If `userAuthenticated` is `true`, line 67 saves the account number entered by the user (i.e., `accountNumber`) in the ATM attribute `currentAccountNumber`. The other ATM methods use this variable whenever an ATM session requires access to the user's account number. If `userAuthenticated` is `false`, lines 70–71 use the screen's `displayMessageLine` method to indicate that an invalid account number and/or PIN was entered and the user must try again. We set `currentAccountNumber` only after authenticating the user's account number and the associated PIN—if the database could not authenticate the user, `currentAccountNumber` remains 0.

After method `run` attempts to authenticate the user (line 42), if `userAuthenticated` is still `false`, the `while` loop in lines 39–43 executes again. If `userAuthenticated` is now `true`, the loop terminates and control continues with line 45, which calls class ATM's utility method `performTransactions`.

### *Performing Transactions*

Method `performTransactions` (lines 75–112) carries out an ATM session for an authenticated user. Line 78 declares a local `Transaction` variable to which we'll assign a `BalanceInquiry`, `Withdrawal` or `Deposit` object representing the ATM transaction the user selected. We use a `Transaction` variable here to allow us to take advantage of polymorphism. Also, we name this variable after the *role name* included in the class diagram of Fig. 12.7—`currentTransaction`. Line 80 declares another local variable—a `boolean` called `userExited` that keeps track of whether the user has chosen to exit. This variable controls a `while` loop (lines 83–111) that allows the user to execute an unlimited number of transactions before choosing to exit. Within this loop, line 86 displays the main menu and obtains the user's menu selection by calling an ATM utility method `displayMainMenu` (declared in lines 115–124). This method displays the main menu by invoking methods of the ATM's screen and returns a menu selection obtained from the user through the ATM's keypad. Line 86 stores the user's selection returned by `displayMainMenu` in local variable `mainMenuSelection`.

After obtaining a main menu selection, method `performTransactions` uses a `switch` statement (lines 89–110) to respond to the selection appropriately. If `mainMenuSelection`

is equal to any of the three integer constants representing transaction types (i.e., if the user chose to perform a transaction), lines 97–98 call utility method `createTransaction` (declared in lines 127–149) to return a newly instantiated object of the type that corresponds to the selected transaction. Variable `currentTransaction` is assigned the reference returned by `createTransaction`, then line 100 invokes method `execute` of this transaction to execute it. We'll discuss `Transaction` method `execute` and the three `Transaction` subclasses shortly. We assign the `Transaction` variable `currentTransaction` an object of one of the three `Transaction` subclasses so that we can execute transactions *polymorphically*. For example, if the user chooses to perform a balance inquiry, `mainMenuSelection` equals `BALANCE_INQUIRY`, leading `createTransaction` to return a `BalanceInquiry` object. Thus, `currentTransaction` refers to a `BalanceInquiry`, and invoking `currentTransaction.execute()` results in `BalanceInquiry`'s version of `execute` being called.

### *Creating a Transaction*

Method `createTransaction` (lines 127–149) uses a `switch` statement (lines 132–146) to instantiate a new `Transaction` subclass object of the type indicated by the parameter `type`. Recall that method `performTransactions` passes `mainMenuSelection` to this method only when `mainMenuSelection` contains a value corresponding to one of the three transaction types. Therefore `type` is `BALANCE_INQUIRY`, `WITHDRAWAL` or `DEPOSIT`. Each case in the `switch` statement instantiates a new object by calling the appropriate `Transaction` subclass constructor. Each constructor has a unique parameter list, based on the specific data required to initialize the subclass object. A `BalanceInquiry` requires only the account number of the current user and references to the ATM's screen and the `bankDatabase`. In addition to these parameters, a `Withdrawal` requires references to the ATM's keypad and `cashDispenser`, and a `Deposit` requires references to the ATM's keypad and `depositSlot`. We discuss the transaction classes in more detail in Sections 13.4.8–13.4.11.

### *Exiting the Main Menu and Processing Invalid Selections*

After executing a transaction (line 100 in `performTransactions`), `userExited` remains `false` and lines 83–111 repeat, returning the user to the main menu. However, if a user does not perform a transaction and instead selects the main menu option to exit, line 104 sets `userExited` to `true`, causing the condition of the `while` loop (`!userExited`) to become `false`. This `while` is the final statement of method `performTransactions`, so control returns to the calling method `run`. If the user enters an invalid main menu selection (i.e., not an integer from 1–4), lines 107–108 display an appropriate error message, `userExited` remains `false` and the user returns to the main menu to try again.

### *Awaiting the Next ATM User*

When `performTransactions` returns control to method `run`, the user has chosen to exit the system, so lines 46–47 reset the ATM's attributes `userAuthenticated` and `currentAccountNumber` to prepare for the next ATM user. Line 48 displays a goodbye message before the ATM starts over and welcomes the next user.

## 13.4.2 Class Screen

`Class Screen` (Fig. 13.14) represents the screen of the ATM and encapsulates all aspects of displaying output to the user. `Class Screen` approximates a real ATM's screen with a computer monitor and outputs text messages using standard console output methods

`System.out.print`, `System.out.println` and `System.out.printf`. In this case study, we designed class `Screen` to have one operation—`displayMessage`. For greater flexibility in displaying messages to the `Screen`, we now declare three `Screen` methods—`displayMessage`, `displayMessageLine` and `displayDollarAmount`.

---

```

1 // Screen.java
2 // Represents the screen of the ATM
3
4 public class Screen
5 {
6     // display a message without a carriage return
7     public void displayMessage( String message )
8     {
9         System.out.print( message );
10    } // end method displayMessage
11
12    // display a message with a carriage return
13    public void displayMessageLine( String message )
14    {
15        System.out.println( message );
16    } // end method displayMessageLine
17
18    // displays a dollar amount
19    public void displayDollarAmount( double amount )
20    {
21        System.out.printf( "$%,.2f", amount );
22    } // end method displayDollarAmount
23 } // end class Screen

```

---

**Fig. 13.14** | Class `Screen` represents the screen of the ATM.

Method `displayMessage` (lines 7–10) takes a `String` argument and prints it to the console. The cursor stays on the same line, making this method appropriate for displaying prompts to the user. Method `displayMessageLine` (lines 13–16) does the same using `System.out.println`, which outputs a newline to move the cursor to the next line. Finally, method `displayDollarAmount` (lines 19–22) outputs a properly formatted dollar amount (e.g., \$1,234.56). Line 21 uses `System.out.printf` to output a `double` value formatted with commas to increase readability and two decimal places.

### 13.4.3 Class Keypad

Class `Keypad` (Fig. 13.15) represents the keypad of the ATM and is responsible for receiving all user input. Recall that we’re simulating this hardware, so we use the computer’s keyboard to approximate the keypad. We use class `Scanner` to obtain console input from the user. A computer keyboard contains many keys not found on the ATM’s keypad. However, we assume that the user presses only the keys on the computer keyboard that also appear on the keypad—the keys numbered 0–9 and the *Enter* key.

Line 3 of class `Keypad` imports class `Scanner` for use in class `Keypad`. Line 7 declares `Scanner` variable `input` as an instance variable. Line 12 in the constructor creates a new `Scanner` object that reads input from the standard input stream (`System.in`) and assigns the object’s reference to variable `input`. Method `getInput` (lines 16–19) invokes `Scanner`

---

```

1 // Keypad.java
2 // Represents the keypad of the ATM
3 import java.util.Scanner; // program uses Scanner to obtain user input
4
5 public class Keypad
6 {
7     private Scanner input; // reads data from the command line
8
9     // no-argument constructor initializes the Scanner
10    public Keypad()
11    {
12        input = new Scanner( System.in );
13    } // end no-argument Keypad constructor
14
15    // return an integer value entered by user
16    public int getInput()
17    {
18        return input.nextInt(); // we assume that user enters an integer
19    } // end method getInput
20 } // end class Keypad

```

---

**Fig. 13.15** | Class Keypad represents the ATM's keypad.

method `nextInt` (line 18) to return the next integer input by the user. [*Note:* Method `nextInt` can throw an `InputMismatchException` if the user enters non-integer input. Because the real ATM's keypad permits only integer input, we assume that no exception will occur and do not attempt to fix this problem. See Chapter 11, *Exception Handling: A Deeper Look*, for information on catching exceptions.] Recall that `nextInt` obtains all the input used by the ATM. Keypad's `getInput` method simply returns the integer input by the user. If a client of class Keypad requires input that satisfies some criteria (i.e., a number corresponding to a valid menu option), the client must perform the error checking.

### 13.4.4 Class CashDispenser

Class `CashDispenser` (Fig. 13.16) represents the cash dispenser of the ATM. Line 7 declares constant `INITIAL_COUNT`, which indicates the initial count of bills in the cash dispenser when the ATM starts (i.e., 500). Line 8 implements attribute `count` (modeled in Fig. 13.10), which keeps track of the number of bills remaining in the `CashDispenser` at any time. The constructor (lines 11–14) sets `count` to the initial count. `CashDispenser` has two public methods—`dispenseCash` (lines 17–21) and `isSufficientCashAvailable` (lines 24–32). The class trusts that a client (i.e., `Withdrawal`) calls `dispenseCash` only after establishing that sufficient cash is available by calling `isSufficientCashAvailable`. Thus, `dispenseCash` simply simulates dispensing the requested amount without checking whether sufficient cash is available.

---

```

1 // CashDispenser.java
2 // Represents the cash dispenser of the ATM
3

```

---

**Fig. 13.16** | Class CashDispenser represents the ATM's cash dispenser. (Part 1 of 2.)

```

4 public class CashDispenser
5 {
6     // the default initial number of bills in the cash dispenser
7     private final static int INITIAL_COUNT = 500;
8     private int count; // number of $20 bills remaining
9
10    // no-argument CashDispenser constructor initializes count to default
11    public CashDispenser()
12    {
13        count = INITIAL_COUNT; // set count attribute to default
14    } // end CashDispenser constructor
15
16    // simulates dispensing of specified amount of cash
17    public void dispenseCash( int amount )
18    {
19        int billsRequired = amount / 20; // number of $20 bills required
20        count -= billsRequired; // update the count of bills
21    } // end method dispenseCash
22
23    // indicates whether cash dispenser can dispense desired amount
24    public boolean isSufficientCashAvailable( int amount )
25    {
26        int billsRequired = amount / 20; // number of $20 bills required
27
28        if ( count >= billsRequired )
29            return true; // enough bills available
30        else
31            return false; // not enough bills available
32    } // end method isSufficientCashAvailable
33 } // end class CashDispenser

```

**Fig. 13.16** | Class `CashDispenser` represents the ATM's cash dispenser. (Part 2 of 2.)

Method `isSufficientCashAvailable` (lines 24–32) has a parameter `amount` that specifies the amount of cash in question. Line 26 calculates the number of \$20 bills required to dispense the specified amount. The ATM allows the user to choose only withdrawal amounts that are multiples of \$20, so we divide `amount` by 20 to obtain the number of `billsRequired`. Lines 28–31 return `true` if the `CashDispenser`'s `count` is greater than or equal to `billsRequired` (i.e., enough bills are available) and `false` otherwise (i.e., not enough bills). For example, if a user wishes to withdraw \$80 (i.e., `billsRequired` is 4), but only three bills remain (i.e., `count` is 3), the method returns `false`.

Method `dispenseCash` (lines 17–21) simulates cash dispensing. If our system were hooked up to a real hardware cash dispenser, this method would interact with the device to physically dispense cash. Our version of the method simply decreases the count of bills remaining by the number required to dispense the specified amount (line 20). It's the responsibility of the client of the class (i.e., `Withdrawal`) to inform the user that cash has been dispensed—`CashDispenser` cannot interact directly with `Screen`.

### 13.4.5 Class `DepositSlot`

Class `DepositSlot` (Fig. 13.17) represents the ATM's deposit slot. Like class `CashDispenser`, class `DepositSlot` merely simulates the functionality of a real hardware deposit

slot. `DepositSlot` has no attributes and only one method—`isEnvelopeReceived` (lines 8–11)—which indicates whether a deposit envelope was received.

---

```

1 // DepositSlot.java
2 // Represents the deposit slot of the ATM
3
4 public class DepositSlot
5 {
6     // indicates whether envelope was received (always returns true,
7     // because this is only a software simulation of a real deposit slot)
8     public boolean isEnvelopeReceived()
9     {
10         return true; // deposit envelope was received
11     } // end method isEnvelopeReceived
12 } // end class DepositSlot

```

---

**Fig. 13.17** | Class `DepositSlot` represents the ATM's deposit slot.

Recall from the requirements document that the ATM allows the user up to two minutes to insert an envelope. The current version of method `isEnvelopeReceived` simply returns `true` immediately (line 10), because this is only a software simulation, and we assume that the user has inserted an envelope within the required time frame. If an actual hardware deposit slot were connected to our system, method `isEnvelopeReceived` might be implemented to wait for a maximum of two minutes to receive a signal from the hardware deposit slot indicating that the user has indeed inserted a deposit envelope. If `isEnvelopeReceived` were to receive such a signal within two minutes, the method would return `true`. If two minutes elapsed and the method still had not received a signal, then the method would return `false`.

### 13.4.6 Class Account

Class `Account` (Fig. 13.18) represents a bank account. Each `Account` has four attributes (modeled in Fig. 13.10)—`accountNumber`, `pin`, `availableBalance` and `totalBalance`. Lines 6–9 implement these attributes as private fields. Variable `availableBalance` represents the amount of funds available for withdrawal. Variable `totalBalance` represents the amount of funds available, plus the amount of deposited funds still pending confirmation or clearance.

---

```

1 // Account.java
2 // Represents a bank account
3
4 public class Account
5 {
6     private int accountNumber; // account number
7     private int pin; // PIN for authentication
8     private double availableBalance; // funds available for withdrawal
9     private double totalBalance; // funds available + pending deposits

```

---

**Fig. 13.18** | Class `Account` represents a bank account. (Part 1 of 2.)

```
10
11 // Account constructor initializes attributes
12 public Account( int theAccountNumber, int thePIN,
13               double theAvailableBalance, double theTotalBalance )
14 {
15     accountNumber = theAccountNumber;
16     pin = thePIN;
17     availableBalance = theAvailableBalance;
18     totalBalance = theTotalBalance;
19 } // end Account constructor
20
21 // determines whether a user-specified PIN matches PIN in Account
22 public boolean validatePIN( int userPIN )
23 {
24     if ( userPIN == pin )
25         return true;
26     else
27         return false;
28 } // end method validatePIN
29
30 // returns available balance
31 public double getAvailableBalance()
32 {
33     return availableBalance;
34 } // end getAvailableBalance
35
36 // returns the total balance
37 public double getTotalBalance()
38 {
39     return totalBalance;
40 } // end method getTotalBalance
41
42 // credits an amount to the account
43 public void credit( double amount )
44 {
45     totalBalance += amount; // add to total balance
46 } // end method credit
47
48 // debits an amount from the account
49 public void debit( double amount )
50 {
51     availableBalance -= amount; // subtract from available balance
52     totalBalance -= amount; // subtract from total balance
53 } // end method debit
54
55 // returns account number
56 public int getAccountNumber()
57 {
58     return accountNumber;
59 } // end method getAccountNumber
60 } // end class Account
```

**Fig. 13.18** | Class Account represents a bank account. (Part 2 of 2.)

The `Account` class has a constructor (lines 12–19) that takes an account number, the PIN established for the account, the account’s initial available balance and the account’s initial total balance as arguments. Lines 15–18 assign these values to the class’s attributes (i.e., fields).

Method `validatePIN` (lines 22–28) determines whether a user-specified PIN (i.e., parameter `userPIN`) matches the PIN associated with the account (i.e., attribute `pin`). Recall that we modeled this method’s parameter `userPIN` in Fig. 12.19. If the two PINs match, the method returns `true` (line 25); otherwise, it returns `false` (line 27).

Methods `getAvailableBalance` (lines 31–34) and `getTotalBalance` (lines 37–40) return the values of `double` attributes `availableBalance` and `totalBalance`, respectively.

Method `credit` (lines 43–46) adds an amount of money (i.e., parameter `amount`) to an `Account` as part of a deposit transaction. This method adds the amount only to attribute `totalBalance` (line 45). The money credited to an account during a deposit does *not* become available immediately, so we modify only the total balance. We assume that the bank updates the available balance appropriately at a later time. Our implementation of class `Account` includes only methods required for carrying out ATM transactions. Therefore, we omit the methods that some other bank system would invoke to add to attribute `availableBalance` (to confirm a deposit) or subtract from attribute `totalBalance` (to reject a deposit).

Method `debit` (lines 49–53) subtracts an amount of money (i.e., parameter `amount`) from an `Account` as part of a withdrawal transaction. This method subtracts the amount from *both* attribute `availableBalance` (line 51) and attribute `totalBalance` (line 52), because a withdrawal affects *both* measures of an account balance.

Method `getAccountNumber` (lines 56–59) provides access to an `Account`’s account-number. We include this method in our implementation so that a client of the class (i.e., `BankDatabase`) can identify a particular `Account`. For example, `BankDatabase` contains many `Account` objects, and it can invoke this method on each of its `Account` objects to locate the one with a specific account number.

### 13.4.7 Class `BankDatabase`

Class `BankDatabase` (Fig. 13.19) models the bank’s database with which the ATM interacts to access and modify a user’s account information. We study database access in Chapter 28. For now we model the database as an array. An exercise in Chapter 28 asks you to reimplement this portion of the ATM using an actual database.

---

```

1 // BankDatabase.java
2 // Represents the bank account information database
3
4 public class BankDatabase
5 {
6     private Account[] accounts; // array of Accounts
7
8     // no-argument BankDatabase constructor initializes accounts
9     public BankDatabase()
10    {
```

**Fig. 13.19** | Class `BankDatabase` represents the bank’s account information database. (Part 1 of 3.)

```
11     accounts = new Account[ 2 ]; // just 2 accounts for testing
12     accounts[ 0 ] = new Account( 12345, 54321, 1000.0, 1200.0 );
13     accounts[ 1 ] = new Account( 98765, 56789, 200.0, 200.0 );
14 } // end no-argument BankDatabase constructor
15
16 // retrieve Account object containing specified account number
17 private Account getAccount( int accountNumber )
18 {
19     // loop through accounts searching for matching account number
20     for ( Account currentAccount : accounts )
21     {
22         // return current account if match found
23         if ( currentAccount.getAccountNumber() == accountNumber )
24             return currentAccount;
25     } // end for
26
27     return null; // if no matching account was found, return null
28 } // end method getAccount
29
30 // determine whether user-specified account number and PIN match
31 // those of an account in the database
32 public boolean authenticateUser( int userAccountNumber, int userPIN )
33 {
34     // attempt to retrieve the account with the account number
35     Account userAccount = getAccount( userAccountNumber );
36
37     // if account exists, return result of Account method validatePIN
38     if ( userAccount != null )
39         return userAccount.validatePIN( userPIN );
40     else
41         return false; // account number not found, so return false
42 } // end method authenticateUser
43
44 // return available balance of Account with specified account number
45 public double getAvailableBalance( int userAccountNumber )
46 {
47     return getAccount( userAccountNumber ).getAvailableBalance();
48 } // end method getAvailableBalance
49
50 // return total balance of Account with specified account number
51 public double getTotalBalance( int userAccountNumber )
52 {
53     return getAccount( userAccountNumber ).getTotalBalance();
54 } // end method getTotalBalance
55
56 // credit an amount to Account with specified account number
57 public void credit( int userAccountNumber, double amount )
58 {
59     getAccount( userAccountNumber ).credit( amount );
60 } // end method credit
61
```

**Fig. 13.19** | Class BankDatabase represents the bank's account information database. (Part 2 of 3.)

---

```

62 // debit an amount from Account with specified account number
63 public void debit( int userAccountNumber, double amount )
64 {
65     getAccount( userAccountNumber ).debit( amount );
66 } // end method debit
67 } // end class BankDatabase

```

---

**Fig. 13.19** | Class `BankDatabase` represents the bank’s account information database. (Part 3 of 3.)

We determine one reference-type attribute for class `BankDatabase` based on its composition relationship with class `Account`. Recall from Fig. 13.9 that a `BankDatabase` is composed of zero or more objects of class `Account`. Line 6 implements attribute `accounts`—an array of `Account` objects—to implement this composition relationship. Class `BankDatabase` has a no-argument constructor (lines 9–14) that initializes `accounts` to contain a set of new `Account` objects. For the sake of testing the system, we declare `accounts` to hold just two array elements (line 11), which we instantiate as new `Account` objects with test data (lines 12–13). The `Account` constructor has four parameters—the account number, the PIN assigned to the account, the initial available balance and the initial total balance. Recall that class `BankDatabase` serves as an intermediary between class `ATM` and the actual `Account` objects that contain a user’s account information. Thus, the methods of class `BankDatabase` do nothing more than invoke the corresponding methods of the `Account` object belonging to the current `ATM` user.

We include private utility method `getAccount` (lines 17–28) to allow the `BankDatabase` to obtain a reference to a particular `Account` within array `accounts`. To locate the user’s `Account`, the `BankDatabase` compares the value returned by method `getAccountNumber` for each element of `accounts` to a specified account number until it finds a match. Lines 20–25 traverse the `accounts` array. If the account number of `currentAccount` equals the value of parameter `accountNumber`, the method immediately returns the `currentAccount`. If no account has the given account number, then line 27 returns `null`.

Method `authenticateUser` (lines 32–42) proves or disproves the identity of an `ATM` user. This method takes a user-specified account number and PIN as arguments and indicates whether they match the account number and PIN of an `Account` in the database. Line 35 calls method `getAccount`, which returns either an `Account` with `userAccountNumber` as its account number or `null` to indicate that `userAccountNumber` is invalid. If `getAccount` returns an `Account` object, line 39 returns the `boolean` value returned by that object’s `validatePIN` method. `BankDatabase`’s `authenticateUser` method does not perform the PIN comparison itself—rather, it forwards `userPIN` to the `Account` object’s `validatePIN` method to do so. The value returned by `Account` method `validatePIN` indicates whether the user-specified PIN matches the PIN of the user’s `Account`, so method `authenticateUser` simply returns this value to the class’s client (i.e., `ATM`).

`BankDatabase` trusts the `ATM` to invoke method `authenticateUser` and receive a return value of `true` before allowing the user to perform transactions. `BankDatabase` also trusts that each `Transaction` object created by the `ATM` contains the valid account number of the current authenticated user and that this is the account number passed to the remaining `BankDatabase` methods as argument `userAccountNumber`. Methods `getAvailableBalance` (lines 45–48), `getTotalBalance` (lines 51–54), `credit` (lines 57–60) and

debit (lines 63–66) therefore simply retrieve the user’s Account object with utility method `getAccount`, then invoke the appropriate Account method on that object. We know that the calls to `getAccount` from these methods will never return `null`, because `userAccountNumber` must refer to an existing Account. Methods `getAvailableBalance` and `getTotalBalance` return the values returned by the corresponding Account methods. Also, `credit` and `debit` simply redirect parameter amount to the Account methods they invoke.

### 13.4.8 Class Transaction

Class Transaction (Fig. 13.20) is an abstract superclass that represents the notion of an ATM transaction. It contains the common features of subclasses `BalanceInquiry`, `Withdrawal` and `Deposit`. This class expands upon the “skeleton” code first developed in Section 13.3. Line 4 declares this class to be abstract. Lines 6–8 declare the class’s private attributes. Recall from the class diagram of Fig. 13.10 that class Transaction contains an attribute `accountNumber` (line 6) that indicates the account involved in the Transaction. We derive attributes `screen` (line 7) and `bankDatabase` (line 8) from class Transaction’s associations modeled in Fig. 13.9—all transactions require access to the ATM’s screen and the bank’s database.

---

```

1 // Transaction.java
2 // Abstract superclass Transaction represents an ATM transaction
3
4 public abstract class Transaction
5 {
6     private int accountNumber; // indicates account involved
7     private Screen screen; // ATM's screen
8     private BankDatabase bankDatabase; // account info database
9
10    // Transaction constructor invoked by subclasses using super()
11    public Transaction( int userAccountNumber, Screen atmScreen,
12                      BankDatabase atmBankDatabase )
13    {
14        accountNumber = userAccountNumber;
15        screen = atmScreen;
16        bankDatabase = atmBankDatabase;
17    } // end Transaction constructor
18
19    // return account number
20    public int getAccountNumber()
21    {
22        return accountNumber;
23    } // end method getAccountNumber
24
25    // return reference to screen
26    public Screen getScreen()
27    {
28        return screen;
29    } // end method getScreen
30

```

**Fig. 13.20** | Abstract superclass Transaction represents an ATM transaction. (Part I of 2.)

---

```

31 // return reference to bank database
32 public BankDatabase getBankDatabase()
33 {
34     return bankDatabase;
35 } // end method getBankDatabase
36
37 // perform the transaction (overridden by each subclass)
38 abstract public void execute();
39 } // end class Transaction

```

---

**Fig. 13.20** | Abstract superclass Transaction represents an ATM transaction. (Part 2 of 2.)

Class Transaction has a constructor (lines 11–17) that takes as arguments the current user’s account number and references to the ATM’s screen and the bank’s database. Because Transaction is an *abstract* class, this constructor will be called only by the constructors of the Transaction subclasses.

The class has three public *get* methods—getAccountNumber (lines 20–23), getScreen (lines 26–29) and getBankDatabase (lines 32–35). These are inherited by Transaction subclasses and used to gain access to class Transaction’s private attributes.

Class Transaction also declares abstract method execute (line 38). It does not make sense to provide this method’s implementation, because a generic transaction cannot be executed. So, we declare this method abstract and force each Transaction subclass to provide a concrete implementation that executes that particular type of transaction.

### 13.4.9 Class BalanceInquiry

Class BalanceInquiry (Fig. 13.21) extends Transaction and represents a balance-inquiry ATM transaction. BalanceInquiry does not have any attributes of its own, but it inherits Transaction attributes accountNumber, screen and bankDatabase, which are accessible through Transaction’s public *get* methods. The BalanceInquiry constructor takes arguments corresponding to these attributes and simply forwards them to Transaction’s constructor using super (line 10).

---

```

1 // BalanceInquiry.java
2 // Represents a balance inquiry ATM transaction
3
4 public class BalanceInquiry extends Transaction
5 {
6     // BalanceInquiry constructor
7     public BalanceInquiry( int userAccountNumber, Screen atmScreen,
8         BankDatabase atmBankDatabase )
9     {
10        super( userAccountNumber, atmScreen, atmBankDatabase );
11    } // end BalanceInquiry constructor
12
13    // performs the transaction
14    @Override
15    public void execute()
16    {

```

---

**Fig. 13.21** | Class BalanceInquiry represents a balance-inquiry ATM transaction. (Part 1 of 2.)

```

17     // get references to bank database and screen
18     BankDatabase bankDatabase = getBankDatabase();
19     Screen screen = getScreen();
20
21     // get the available balance for the account involved
22     double availableBalance =
23         bankDatabase.getAvailableBalance( getAccountNumber() );
24
25     // get the total balance for the account involved
26     double totalBalance =
27         bankDatabase.getTotalBalance( getAccountNumber() );
28
29     // display the balance information on the screen
30     screen.displayMessageLine( "\nBalance Information:" );
31     screen.displayMessage( " - Available balance: " );
32     screen.displayDollarAmount( availableBalance );
33     screen.displayMessage( "\n - Total balance:      " );
34     screen.displayDollarAmount( totalBalance );
35     screen.displayMessageLine( "" );
36 } // end method execute
37 } // end class BalanceInquiry

```

**Fig. 13.21** | Class `BalanceInquiry` represents a balance-inquiry ATM transaction. (Part 2 of 2.)

Class `BalanceInquiry` overrides `Transaction`'s abstract method `execute` to provide a concrete implementation (lines 14–36) that performs the steps involved in a balance inquiry. Lines 18–19 get references to the bank database and the ATM's screen by invoking methods inherited from superclass `Transaction`. Lines 22–23 retrieve the available balance of the account involved by invoking method `getAvailableBalance` of `BankDatabase`. Line 23 uses inherited method `getAccountNumber` to get the account number of the current user, which it then passes to `getAvailableBalance`. Lines 26–27 retrieve the total balance of the current user's account. Lines 30–35 display the balance information on the ATM's screen. Recall that `displayDollarAmount` takes a `double` argument and outputs it to the screen formatted as a dollar amount. For example, if a user's `availableBalance` is 1000.5, line 32 outputs \$1,000.50. Line 35 inserts a blank line of output to separate the balance information from subsequent output (i.e., the main menu repeated by class `ATM` after executing the `BalanceInquiry`).

### 13.4.10 Class `Withdrawal`

Class `Withdrawal` (Fig. 13.22) extends `Transaction` and represents a withdrawal ATM transaction. This class expands upon the “skeleton” code for this class developed in Fig. 13.12. Recall from the class diagram of Fig. 13.10 that class `Withdrawal` has one attribute, `amount`, which line 6 implements as an `int` field. Figure 13.9 models associations between class `Withdrawal` and classes `Keypad` and `CashDispenser`, for which lines 7–8 implement reference-type attributes `keypad` and `cashDispenser`, respectively. Line 11 declares a constant corresponding to the cancel menu option. We'll soon discuss how the class uses this constant.

```
1 // Withdrawal.java
2 // Represents a withdrawal ATM transaction
3
4 public class Withdrawal extends Transaction
5 {
6     private int amount; // amount to withdraw
7     private Keypad keypad; // reference to keypad
8     private CashDispenser cashDispenser; // reference to cash dispenser
9
10    // constant corresponding to menu option to cancel
11    private final static int CANCELED = 6;
12
13    // Withdrawal constructor
14    public Withdrawal( int userAccountNumber, Screen atmScreen,
15        BankDatabase atmBankDatabase, Keypad atmKeypad,
16        CashDispenser atmCashDispenser )
17    {
18        // initialize superclass variables
19        super( userAccountNumber, atmScreen, atmBankDatabase );
20
21        // initialize references to keypad and cash dispenser
22        keypad = atmKeypad;
23        cashDispenser = atmCashDispenser;
24    } // end Withdrawal constructor
25
26    // perform transaction
27    @Override
28    public void execute()
29    {
30        boolean cashDispensed = false; // cash was not dispensed yet
31        double availableBalance; // amount available for withdrawal
32
33        // get references to bank database and screen
34        BankDatabase bankDatabase = getBankDatabase();
35        Screen screen = getScreen();
36
37        // loop until cash is dispensed or the user cancels
38        do
39        {
40            // obtain a chosen withdrawal amount from the user
41            amount = displayMenuOfAmounts();
42
43            // check whether user chose a withdrawal amount or canceled
44            if ( amount != CANCELED )
45            {
46                // get available balance of account involved
47                availableBalance =
48                    bankDatabase.getAvailableBalance( getAccountNumber() );
49
50                // check whether the user has enough money in the account
51                if ( amount <= availableBalance )
52                {
```

**Fig. 13.22** | Class `Withdrawal` represents a withdrawal ATM transaction. (Part 1 of 3.)

```

53         // check whether the cash dispenser has enough money
54         if ( cashDispenser.isSufficientCashAvailable( amount ) )
55         {
56             // update the account involved to reflect the withdrawal
57             bankDatabase.debit( getAccountNumber(), amount );
58
59             cashDispenser.dispenseCash( amount ); // dispense cash
60             cashDispensed = true; // cash was dispensed
61
62             // instruct user to take cash
63             screen.displayMessageLine( "\nYour cash has been" +
64                 " dispensed. Please take your cash now." );
65         } // end if
66         else // cash dispenser does not have enough cash
67             screen.displayMessageLine(
68                 "\nInsufficient cash available in the ATM." +
69                 "\n\nPlease choose a smaller amount." );
70     } // end if
71     else // not enough money available in user's account
72     {
73         screen.displayMessageLine(
74             "\nInsufficient funds in your account." +
75             "\n\nPlease choose a smaller amount." );
76     } // end else
77 } // end if
78 else // user chose cancel menu option
79 {
80     screen.displayMessageLine( "\nCanceling transaction..." );
81     return; // return to main menu because user canceled
82 } // end else
83 } while ( !cashDispensed );
84
85 } // end method execute
86
87 // display a menu of withdrawal amounts and the option to cancel;
88 // return the chosen amount or 0 if the user chooses to cancel
89 private int displayMenuOfAmounts()
90 {
91     int userChoice = 0; // local variable to store return value
92
93     Screen screen = getScreen(); // get screen reference
94
95     // array of amounts to correspond to menu numbers
96     int[] amounts = { 0, 20, 40, 60, 100, 200 };
97
98     // loop while no valid choice has been made
99     while ( userChoice == 0 )
100     {
101         // display the withdrawal menu
102         screen.displayMessageLine( "\nWithdrawal Menu:" );
103         screen.displayMessageLine( "1 - $20" );
104         screen.displayMessageLine( "2 - $40" );
105         screen.displayMessageLine( "3 - $60" );

```

**Fig. 13.22** | Class `Withdrawal` represents a withdrawal ATM transaction. (Part 2 of 3.)

```

106     screen.displayMessageLine( "4 - $100" );
107     screen.displayMessageLine( "5 - $200" );
108     screen.displayMessageLine( "6 - Cancel transaction" );
109     screen.sendMessage( "\nChoose a withdrawal amount: " );
110
111     int input = keypad.getInput(); // get user input through keypad
112
113     // determine how to proceed based on the input value
114     switch ( input )
115     {
116     case 1: // if the user chose a withdrawal amount
117     case 2: // (i.e., chose option 1, 2, 3, 4 or 5), return the
118     case 3: // corresponding amount from amounts array
119     case 4:
120     case 5:
121         userChoice = amounts[ input ]; // save user's choice
122         break;
123     case CANCELED: // the user chose to cancel
124         userChoice = CANCELED; // save user's choice
125         break;
126     default: // the user did not enter a value from 1-6
127         screen.displayMessageLine(
128             "\nInvalid selection. Try again." );
129     } // end switch
130 } // end while
131
132     return userChoice; // return withdrawal amount or CANCELED
133 } // end method displayMenuOfAmounts
134 } // end class Withdrawal

```

**Fig. 13.22** | Class `Withdrawal` represents a withdrawal ATM transaction. (Part 3 of 3.)

Class `Withdrawal`'s constructor (lines 14–24) has five parameters. It uses `super` to pass parameters `userAccountNumber`, `atmScreen` and `atmBankDatabase` to superclass `Transaction`'s constructor to set the attributes that `Withdrawal` inherits from `Transaction`. The constructor also takes references `atmKeypad` and `atmCashDispenser` as parameters and assigns them to reference-type attributes `keypad` and `cashDispenser`.

Class `Withdrawal` overrides `Transaction` method `execute` with a concrete implementation (lines 27–85) that performs the steps of a withdrawal. Line 30 declares and initializes a local `boolean` variable `cashDispensed`, which indicates whether cash has been dispensed (i.e., whether the transaction has completed successfully) and is initially `false`. Line 31 declares local `double` variable `availableBalance`, which will store the user's available balance during a withdrawal transaction. Lines 34–35 get references to the bank database and the ATM's screen by invoking methods inherited from superclass `Transaction`.

Lines 38–83 contain a `do...while` that executes its body until cash is dispensed (i.e., until `cashDispensed` becomes `true`) or until the user chooses to cancel (in which case, the loop terminates). We use this loop to continuously return the user to the start of the transaction if an error occurs (i.e., the requested withdrawal amount is greater than the user's available balance or greater than the amount of cash in the cash dispenser). Line 41 displays a menu of withdrawal amounts and obtains a user selection by calling private utility method `displayMenuOfAmounts` (declared in lines 89–133). This method displays the

menu of amounts and returns either an `int` withdrawal amount or an `int` constant `CANCELED` to indicate that the user has chosen to cancel the transaction.

Method `displayMenuOfAmounts` (lines 89–133) first declares local variable `userChoice` (initially 0) to store the value that the method will return (line 91). Line 93 gets a reference to the screen by calling method `getScreen` inherited from superclass `Transaction`. Line 96 declares an integer array of withdrawal amounts that correspond to the amounts displayed in the withdrawal menu. We ignore the first element in the array (index 0) because the menu has no option 0. The `while` statement at lines 99–130 repeats until `userChoice` takes on a value other than 0. We'll see shortly that this occurs when the user makes a valid selection from the menu. Lines 102–109 display the withdrawal menu on the screen and prompt the user to enter a choice. Line 111 obtains integer input through the keypad. The `switch` statement at lines 114–129 determines how to proceed based on the user's input. If the user selects a number between 1 and 5, line 121 sets `userChoice` to the value of the element in `amounts` at index `input`. For example, if the user enters 3 to withdraw \$60, line 121 sets `userChoice` to the value of `amounts[ 3 ]` (i.e., 60). Line 122 terminates the `switch`. Variable `userChoice` no longer equals 0, so the `while` at lines 99–130 terminates and line 132 returns `userChoice`. If the user selects the cancel menu option, lines 124–125 execute, setting `userChoice` to `CANCELED` and causing the method to return this value. If the user does not enter a valid menu selection, lines 127–128 display an error message and the user is returned to the withdrawal menu.

Line 44 in method `execute` determines whether the user has selected a withdrawal amount or chosen to cancel. If the user cancels, lines 80–81 execute and display an appropriate message to the user before returning control to the calling method (i.e., ATM method `performTransactions`). If the user has chosen a withdrawal amount, lines 47–48 retrieve the available balance of the current user's `Account` and store it in variable `availableBalance`. Next, line 51 determines whether the selected amount is less than or equal to the user's available balance. If it's not, lines 73–75 display an appropriate error message. Control then continues to the end of the `do...while`, and the loop repeats because `cashDispensed` is still `false`. If the user's balance is high enough, the `if` statement at line 54 determines whether the cash dispenser has enough money to satisfy the withdrawal request by invoking the cash dispenser's `isSufficientCashAvailable` method. If this method returns `false`, lines 67–69 display an appropriate error message and the `do...while` repeats. If sufficient cash is available, then the requirements for the withdrawal are satisfied, and line 57 debits `amount` from the user's account in the database. Lines 59–60 then instruct the cash dispenser to dispense the cash to the user and set `cashDispensed` to `true`. Finally, lines 63–64 display a message to the user that cash has been dispensed. Because `cashDispensed` is now `true`, control continues after the `do...while`. No additional statements appear below the loop, so the method returns.

### 13.4.11 Class `Deposit`

Class `Deposit` (Fig. 13.23) extends `Transaction` and represents a deposit transaction. Recall from Fig. 13.10 that class `Deposit` has one attribute `amount`, which line 6 implements as an `int` field. Lines 7–8 create reference attributes `keypad` and `depositSlot` that implement the associations between class `Deposit` and classes `Keypad` and `DepositSlot` modeled in Fig. 13.9. Line 9 declares a constant `CANCELED` that corresponds to the value a user enters to cancel. We'll soon discuss how the class uses this constant.

```

1 // Deposit.java
2 // Represents a deposit ATM transaction
3
4 public class Deposit extends Transaction
5 {
6     private double amount; // amount to deposit
7     private Keypad keypad; // reference to keypad
8     private DepositSlot depositSlot; // reference to deposit slot
9     private final static int CANCELED = 0; // constant for cancel option
10
11 // Deposit constructor
12 public Deposit( int userAccountNumber, Screen atmScreen,
13     BankDatabase atmBankDatabase, Keypad atmKeypad,
14     DepositSlot atmDepositSlot )
15 {
16     // initialize superclass variables
17     super( userAccountNumber, atmScreen, atmBankDatabase );
18
19     // initialize references to keypad and deposit slot
20     keypad = atmKeypad;
21     depositSlot = atmDepositSlot;
22 } // end Deposit constructor
23
24 // perform transaction
25 @Override
26 public void execute()
27 {
28     BankDatabase bankDatabase = getBankDatabase(); // get reference
29     Screen screen = getScreen(); // get reference
30
31     amount = promptForDepositAmount(); // get deposit amount from user
32
33     // check whether user entered a deposit amount or canceled
34     if ( amount != CANCELED )
35     {
36         // request deposit envelope containing specified amount
37         screen.displayMessage(
38             "\nPlease insert a deposit envelope containing " );
39         screen.displayDollarAmount( amount );
40         screen.displayMessageLine( "." );
41
42         // receive deposit envelope
43         boolean envelopeReceived = depositSlot.isEnvelopeReceived();
44
45         // check whether deposit envelope was received
46         if ( envelopeReceived )
47         {
48             screen.displayMessageLine( "\nYour envelope has been " +
49                 "received.\nNOTE: The money just deposited will not " +
50                 "be available until we verify the amount of any " +
51                 "enclosed cash and your checks clear." );
52

```

**Fig. 13.23** | Class `Deposit` represents a deposit ATM transaction. (Part 1 of 2.)

```

53         // credit account to reflect the deposit
54         bankDatabase.credit( getAccountNumber(), amount );
55     } // end if
56     else // deposit envelope not received
57     {
58         screen.displayMessageLine( "\nYou did not insert an " +
59             "envelope, so the ATM has canceled your transaction." );
60     } // end else
61 } // end if
62 else // user canceled instead of entering amount
63 {
64     screen.displayMessageLine( "\nCanceling transaction..." );
65 } // end else
66 } // end method execute
67
68 // prompt user to enter a deposit amount in cents
69 private double promptForDepositAmount()
70 {
71     Screen screen = getScreen(); // get reference to screen
72
73     // display the prompt
74     screen.displayMessage( "\nPlease enter a deposit amount in " +
75         "CENTS (or 0 to cancel): " );
76     int input = keypad.getInput(); // receive input of deposit amount
77
78     // check whether the user canceled or entered a valid amount
79     if ( input == CANCELED )
80         return CANCELED;
81     else
82     {
83         return ( double ) input / 100; // return dollar amount
84     } // end else
85 } // end method promptForDepositAmount
86 } // end class Deposit

```

**Fig. 13.23** | Class `Deposit` represents a deposit ATM transaction. (Part 2 of 2.)

Like `Withdrawal`, class `Deposit` contains a constructor (lines 12–22) that passes three parameters to superclass `Transaction`'s constructor. The constructor also has parameters `atmKeypad` and `atmDepositSlot`, which it assigns to corresponding attributes (lines 20–21).

Method `execute` (lines 25–66) overrides the abstract version in superclass `Transaction` with a concrete implementation that performs the steps required in a deposit transaction. Lines 28–29 get references to the database and the screen. Line 31 prompts the user to enter a deposit amount by invoking private utility method `promptForDepositAmount` (declared in lines 69–85) and sets attribute `amount` to the value returned. Method `promptForDepositAmount` asks the user to enter a deposit amount as an integer number of cents (because the ATM's keypad does not contain a decimal point; this is consistent with many real ATMs) and returns the `double` value representing the dollar amount to be deposited.

Line 71 in method `promptForDepositAmount` gets a reference to the ATM's screen. Lines 74–75 display a message asking the user to input a deposit amount as a number of cents or "0" to cancel the transaction. Line 76 receives the user's input from the keypad. Lines 79–84 determine whether the user has entered a real deposit amount or chosen to

cancel. If the latter, line 80 returns the constant `CANCELED`. Otherwise, line 83 returns the deposit amount after converting from the number of cents to a dollar amount by casting input to a `double`, then dividing by 100. For example, if the user enters 125 as the number of cents, line 83 returns 125.0 divided by 100, or 1.25—125 cents is \$1.25.

Lines 34–65 in method `execute` determine whether the user has chosen to cancel the transaction instead of entering a deposit amount. If the user cancels, line 64 displays an appropriate message, and the method returns. If the user enters a deposit amount, lines 37–40 instruct the user to insert a deposit envelope with the correct amount. Recall that `Screen` method `displayDollarAmount` outputs a `double` formatted as a dollar amount.

Line 43 sets a local `boolean` variable to the value returned by `depositSlot`'s `isEnvelopeReceived` method, indicating whether a deposit envelope has been received. Recall that we coded method `isEnvelopeReceived` (lines 8–11 of Fig. 13.17) to always return `true`, because we're simulating the functionality of the deposit slot and assume that the user always inserts an envelope. However, we code method `execute` of class `Deposit` to test for the possibility that the user does not insert an envelope—good software engineering demands that programs account for *all* possible return values. Thus, class `Deposit` is prepared for future versions of `isEnvelopeReceived` that could return `false`. Lines 48–54 execute if the deposit slot receives an envelope. Lines 48–51 display an appropriate message to the user. Line 54 then credits the deposit amount to the user's account in the database. Lines 58–59 will execute if the deposit slot does not receive a deposit envelope. In this case, we display a message to the user stating that the ATM has canceled the transaction. The method then returns without modifying the user's account.

### 13.4.12 Class `ATMCaseStudy`

Class `ATMCaseStudy` (Fig. 13.24) is a simple class that allows us to start, or “turn on,” the ATM and test the implementation of our ATM system model. Class `ATMCaseStudy`'s `main` method (lines 7–11) does nothing more than instantiate a new ATM object named `theATM` (line 9) and invoke its `run` method (line 10) to start the ATM.

---

```

1 // ATMCaseStudy.java
2 // Driver program for the ATM case study
3
4 public class ATMCaseStudy
5 {
6     // main method creates and runs the ATM
7     public static void main( String[] args )
8     {
9         ATM theATM = new ATM();
10        theATM.run();
11    } // end main
12 } // end class ATMCaseStudy

```

---

**Fig. 13.24** | `ATMCaseStudy.java` starts the ATM.

## 13.5 Wrap-Up

In this chapter, you used inheritance to tune the design of the ATM software system, and you fully implemented the ATM in Java. Congratulations on completing the entire ATM

case study! We hope you found this experience to be valuable and that it reinforced many of the object-oriented programming concepts that you've learned. In the next chapter, we take a deeper look at graphical user interfaces (GUIs).

## Answers to Self-Review Exercises

**13.1** True. The minus sign (-) indicates private visibility.

**13.2** b.

**13.3** The design for class `Keypad` yields the code in Fig. 13.25. Recall that class `Keypad` has no attributes for the moment, but attributes may become apparent as we continue the implementation. Also, if we were designing a real ATM, method `getInput` would need to interact with the ATM's keypad hardware. We'll actually read input from the keyboard of a personal computer when we write the complete Java code in Section 13.4.

```

1 // Class Keypad represents an ATM's keypad
2 public class Keypad
3 {
4     // no attributes have been specified yet
5
6     // no-argument constructor
7     public Keypad()
8     {
9     } // end no-argument Keypad constructor
10
11    // operations
12    public int getInput()
13    {
14    } // end method getInput
15 } // end class Keypad

```

**Fig. 13.25** | Java code for class `Keypad` based on Figs. 13.1–13.2.

**13.4** b.

**13.5** False. The UML requires that we italicize abstract class names and method names.

**13.6** The design for class `Transaction` yields the code in Fig. 13.26. The bodies of the class constructor and methods are completed in Section 13.4. When fully implemented, methods `getScreen` and `getBankDatabase` will return superclass `Transaction`'s private reference attributes `screen` and `bankDatabase`, respectively. These methods allow the `Transaction` subclasses to access the ATM's screen and interact with the bank's database.

```

1 // Abstract class Transaction represents an ATM transaction
2 public abstract class Transaction
3 {
4     // attributes
5     private int accountNumber; // indicates account involved
6     private Screen screen; // ATM's screen
7     private BankDatabase bankDatabase; // account info database

```

**Fig. 13.26** | Java code for class `Transaction` based on Figs. 13.9 and 13.10. (Part I of 2.)

```
8
9 // no-argument constructor invoked by subclasses using super()
10 public Transaction()
11 {
12 } // end no-argument Transaction constructor
13
14 // return account number
15 public int getAccountNumber()
16 {
17 } // end method getAccountNumber
18
19 // return reference to screen
20 public Screen getScreen()
21 {
22 } // end method getScreen
23
24 // return reference to bank database
25 public BankDatabase getBankDatabase()
26 {
27 } // end method getBankDatabase
28
29 // abstract method overridden by subclasses
30 public abstract void execute();
31 } // end class Transaction
```

**Fig. 13.26** | Java code for class Transaction based on Figs. 13.9 and 13.10. (Part 2 of 2.)

# GUI Components: Part I

# 14

## Objectives

In this chapter you'll learn:

- How to use Java's elegant, cross-platform Nimbus look-and-feel.
- To build GUIs and handle events generated by user interactions with GUIs.
- To understand the packages containing GUI components, event-handling classes and interfaces.
- To create and manipulate buttons, labels, lists, text fields and panels.
- To handle mouse events and keyboard events.
- To use layout managers to arrange GUI components.

- 14.1 Introduction
- 14.2 Java's New Nimbus Look-and-Feel
- 14.3 Simple GUI-Based Input/Output with JOptionPane
- 14.4 Overview of Swing Components
- 14.5 Displaying Text and Images in a Window
- 14.6 Text Fields and an Introduction to Event Handling with Nested Classes
- 14.7 Common GUI Event Types and Listener Interfaces
- 14.8 How Event Handling Works
- 14.9 JButton
- 14.10 Buttons That Maintain State
  - 14.10.1 JCheckBox
  - 14.10.2 JRadioButton
- 14.11 JComboBox; Using an Anonymous Inner Class for Event Handling
- 14.12 JList
- 14.13 Multiple-Selection Lists
- 14.14 Mouse Event Handling
- 14.15 Adapter Classes
- 14.16 JPanel Subclass for Drawing with the Mouse
- 14.17 Key Event Handling
- 14.18 Introduction to Layout Managers
  - 14.18.1 FlowLayout
  - 14.18.2 BorderLayout
  - 14.18.3 GridLayout
- 14.19 Using Panels to Manage More Complex Layouts
- 14.20 JTextArea
- 14.21 Wrap-Up

Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Making a Difference

## 14.1 Introduction

A **graphical user interface (GUI)** presents a user-friendly mechanism for interacting with an application. A GUI (pronounced “GOO-ee”) gives an application a distinctive “look and feel.” GUIs are built from **GUI components**. These are sometimes called controls or widgets—short for window gadgets. A GUI component is an object with which the user interacts via the mouse, the keyboard or another form of input, such as voice recognition. In this chapter and Chapter 25, GUI Components: Part 2, you’ll learn about many of Java’s so-called **Swing GUI components** from the **javax.swing** package. We cover other GUI components as they’re needed throughout the rest of the book.

### Look-and-Feel Observation 14.1

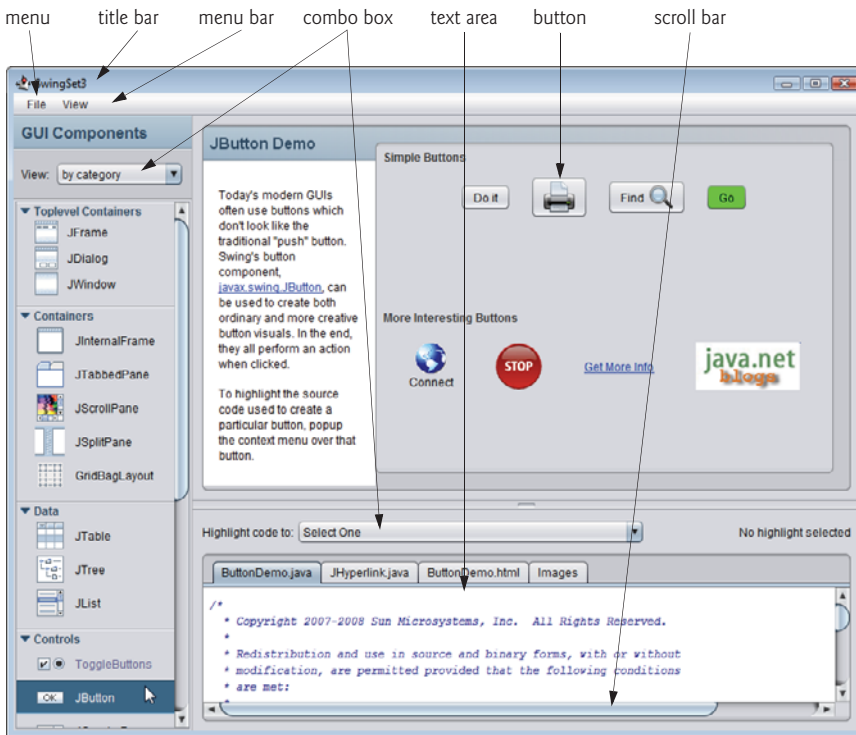

*Providing different applications with consistent, intuitive user-interface components gives users a sense of familiarity with a new application, so that they can learn it more quickly and use it more productively.*

### IDE Support for GUI Design

Many IDEs provide GUI design tools with which you can specify a component’s exact size and location in a visual manner by using the mouse. The IDE generates the GUI code for you. Though this greatly simplifies creating GUIs, each IDE generates this code differently. For this reason, we wrote the GUI code by hand.

### Sample GUI: The SwingSet3 Demo Application

As an example of a GUI, consider Fig. 14.1, which shows the SwingSet3 application that's available at [download.java.net/javadesktop/swingset3/SwingSet3.jnlp](http://download.java.net/javadesktop/swingset3/SwingSet3.jnlp). This application is a nice way for you to browse through the various GUI components provided by Java's Swing GUI APIs. Simply click a component name (e.g., JFrame, JTabbedPane, etc.) in the **GUI Components** area at the left of the window to see a demonstration of the GUI component in the right side of the window. The source code for each demo is shown in the text area at the bottom of the window. We've labeled a few of the GUI components in the application. At the top of the window is a **title bar** that contains the window's title. Below that is a **menu bar** containing **menus** (File and View). In the top-right region of the window is a set of **buttons**—typically, users press buttons to perform tasks. In the **GUI Components** area of the window is a **combo box**; the user can click the down arrow at the right side of the box to select from a list of items. The menus, buttons and combo box are part of the application's GUI. They enable you to interact with the application.

**Fig. 14.1** | SwingSet3 application demonstrates many of Java's Swing GUI components.

## 14.2 Java's New Nimbus Look-and-Feel

In Java SE 6 update 10, Java's elegant, cross-platform look-and-feel known as **Nimbus** was introduced. For GUI screen captures like Fig. 14.1, we've configured our systems to use Nimbus as the default look-and-feel. There are three ways that you can use Nimbus:

1. Set it as the default for all Java applications that run on your computer.
2. Set it as the look-and-feel at the time that you launch an application by passing a command-line argument to the `java` command.
3. Set it as the look-and-feel programmatically in your application (see Section 25.6).

To set Nimbus as the default for all Java applications, you must create a text file named `swing.properties` in the `lib` folder of both your JDK installation folder and your JRE installation folder. Place the following line of code in the file:

```
swing.defaultlaf=com.sun.java.swing.plaf.nimbus.NimbusLookAndFeel
```

For more information on locating these installation folders visit

```
bit.ly/JavaInstallationInstructions
```

In addition to the standalone JRE, there is a JRE nested in your JDK's installation folder. If you're using an IDE that depends on the JDK, you may also need to place the `swing.properties` file in the nested `jre` folder's `lib` folder.

If you prefer to select Nimbus on an application-by-application basis, place the following command-line argument after the `java` command and before the application's name when you run the application:

```
-Dswing.defaultlaf=com.sun.java.swing.plaf.nimbus.NimbusLookAndFeel
```

### 14.3 Simple GUI-Based Input/Output with `JOptionPane`

The applications in Chapters 2–10 display text in the command window and obtain input from the command window. Most applications you use on a daily basis use windows or **dialog boxes** (also called **dialogs**) to interact with the user. For example, an e-mail program allows you to type and read messages in a window the program provides. Dialog boxes are windows in which programs display important messages to the user or obtain information from the user. Java's **`JOptionPane`** class (package `javax.swing`) provides prebuilt dialog boxes for both input and output. These are displayed by invoking static `JOptionPane` methods. Figure 14.2 presents a simple addition application that uses two **input dialogs** to obtain integers from the user and a **message dialog** to display the sum of the integers the user enters.

```

1 // Fig. 14.2: Addition.java
2 // Addition program that uses JOptionPane for input and output.
3 import javax.swing.JOptionPane; // program uses JOptionPane
4
5 public class Addition
6 {
7     public static void main( String[] args )
8     {
9         // obtain user input from JOptionPane input dialogs
10        String firstNumber =
11            JOptionPane.showInputDialog( "Enter first integer" );
12        String secondNumber =
13            JOptionPane.showInputDialog( "Enter second integer" );

```

**Fig. 14.2** | Addition program that uses `JOptionPane` for input and output. (Part I of 2.)

```

14
15 // convert String inputs to int values for use in a calculation
16 int number1 = Integer.parseInt( firstNumber );
17 int number2 = Integer.parseInt( secondNumber );
18
19 int sum = number1 + number2; // add numbers
20
21 // display result in a JOptionPane message dialog
22 JOptionPane.showMessageDialog( null, "The sum is " + sum,
23 "Sum of Two Integers", JOptionPane.PLAIN_MESSAGE );
24 } // end method main
25 } // end class Addition

```

**Fig. 14.2** | Addition program that uses `JOptionPane` for input and output. (Part 2 of 2.)

### Input Dialogs

Line 3 imports class `JOptionPane`. Lines 10–11 declare the local `String` variable `firstNumber` and assign it the result of the call to `JOptionPane` static method **`showInputDialog`**. This method displays an input dialog (see the first screen capture in Fig. 14.2), using the method's `String` argument ("Enter first integer") as a prompt.

### Look-and-Feel Observation 14.2

The prompt in an input dialog typically uses *sentence-style capitalization*—a style that capitalizes only the first letter of the first word in the text unless the word is a proper noun (for example, *Jones*).

The user types characters in the text field, then clicks **OK** or presses the *Enter* key to submit the `String` to the program. Clicking **OK** also **dismisses (hides) the dialog**. [Note: If you type in the text field and nothing appears, activate the text field by clicking it with the mouse.] Unlike `Scanner`, which can be used to input values of *several* types from the user at the keyboard, an input dialog can input only `Strings`. This is typical of most GUI

components. The user can type any characters in the input dialog's text field. Our program assumes that the user enters a valid integer. If the user clicks **Cancel**, `showInputDialog` returns `null`. If the user either types a noninteger value or clicks the **Cancel** button in the input dialog, an exception will occur and the program will not operate correctly. Chapter 11 discussed how to handle such errors. Lines 12–13 display another input dialog that prompts the user to enter the second integer. Each `JOptionPane` dialog that you display is a so called **modal dialog**—while the dialog is on the screen, the user *cannot* interact with the rest of the application.

### Look-and-Feel Observation 14.3

*Do not overuse modal dialogs, as they can reduce the usability of your applications. Use a modal dialog only when it's necessary to prevent users from interacting with the rest of an application until they dismiss the dialog.*

### Converting Strings to int Values

To perform the calculation, we convert the `Strings` that the user entered to `int` values. Recall that the `Integer` class's static method `parseInt` converts its `String` argument to an `int` value. Lines 16–17 assign the converted values to local variables `number1` and `number2`, and line 19 sums these values.

### Message Dialogs

Lines 22–23 use `JOptionPane` static method `showMessageDialog` to display a message dialog (the last screen of Fig. 14.2) containing the sum. The first argument helps the Java application determine where to position the dialog box. A dialog is typically displayed from a GUI application with its own window. The first argument refers to that window (known as the parent window) and causes the dialog to appear centered over the parent (as we'll do in Section 14.9). If the first argument is `null`, the dialog box is displayed at the center of your screen. The second argument is the message to display—in this case, the result of concatenating the `String` "The sum is " and the value of `sum`. The third argument—"Sum of Two Integers"—is the `String` that should appear in the *title bar* at the top of the dialog. The fourth argument—`JOptionPane.PLAIN_MESSAGE`—is the type of message dialog to display. A `PLAIN_MESSAGE` dialog does not display an icon to the left of the message. Class `JOptionPane` provides several overloaded versions of methods `showInputDialog` and `showMessageDialog`, as well as methods that display other dialog types. For complete information on class `JOptionPane`, visit [download.oracle.com/javase/6/docs/api/javax/swing/JOptionPane.html](http://download.oracle.com/javase/6/docs/api/javax/swing/JOptionPane.html).

### Look-and-Feel Observation 14.4

*The title bar of a window typically uses **book-title capitalization**—a style that capitalizes the first letter of each significant word in the text and does not end with any punctuation (for example, *Capitalization in a Book Title*).*

### JOptionPane Message Dialog Constants

The constants that represent the message dialog types are shown in Fig. 14.3. All message dialog types except `PLAIN_MESSAGE` display an icon to the left of the message. These icons provide a visual indication of the message's importance to the user. A `QUESTION_MESSAGE` icon is the *default icon* for an input dialog box (see Fig. 14.2).

| Message dialog type | Icon                                                                              | Description                                                                                                      |
|---------------------|-----------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------|
| ERROR_MESSAGE       |  | Indicates an error.                                                                                              |
| INFORMATION_MESSAGE |  | Indicates an informational message.                                                                              |
| WARNING_MESSAGE     |  | Warns of a potential problem.                                                                                    |
| QUESTION_MESSAGE    |  | Poses a question. This dialog normally requires a response, such as clicking a <b>Yes</b> or a <b>No</b> button. |
| PLAIN_MESSAGE       | no icon                                                                           | A dialog that contains a message, but no icon.                                                                   |

**Fig. 14.3** | JOptionPane static constants for message dialogs.

## 14.4 Overview of Swing Components

Though it's possible to perform input and output using the JOptionPane dialogs, most GUI applications require more elaborate user interfaces. The remainder of this chapter discusses many GUI components that enable application developers to create robust GUIs. Figure 14.4 lists several basic Swing GUI components that we discuss.

| Component | Description                                                                                                                 |
|-----------|-----------------------------------------------------------------------------------------------------------------------------|
| JLabel    | Displays uneditable text and/or icons.                                                                                      |
| TextField | Typically receives input from the user.                                                                                     |
| Button    | Triggers an event when clicked with the mouse.                                                                              |
| CheckBox  | Specifies an option that can be selected or not selected.                                                                   |
| ComboBox  | A drop-down list of items from which the user can make a selection.                                                         |
| List      | A list of items from which the user can make a selection by clicking on any one of them. Multiple elements can be selected. |
| Panel     | An area in which components can be placed and organized.                                                                    |

**Fig. 14.4** | Some basic GUI components.

### *Swing vs. AWT*

There are actually two sets of Java GUI components. In Java's early days, GUIs were built with components from the **Abstract Window Toolkit (AWT)** in package `java.awt`. These look like the native GUI components of the platform on which a Java program executes. For example, a Button object displayed in a Java program running on Microsoft Windows looks like those in other *Windows* applications. On Apple Mac OS X, the Button looks like those in other *Mac* applications. Sometimes, even the manner in which a user can interact with an AWT component *differs between platforms*. The component's appearance and the way in which the user interacts with it are known as its **look-and-feel**.

### Look-and-Feel Observation 14.5

Swing GUI components allow you to specify a uniform look-and-feel for your application across all platforms or to use each platform's custom look-and-feel. An application can even change the look-and-feel during execution to enable users to choose their own preferred look-and-feel.

### Lightweight vs. Heavyweight GUI Components

Most Swing components are **lightweight components**—they're written, manipulated and displayed completely in Java. AWT components are **heavyweight components**, because they rely on the local platform's **windowing system** to determine their functionality and their look-and-feel. Several Swing components are heavyweight components.

### Superclasses of Swing's Lightweight GUI Components

The UML class diagram of Fig. 14.5 shows an inheritance hierarchy of classes from which lightweight Swing components inherit their common attributes and behaviors.

**Fig. 14.5** | Common superclasses of the lightweight Swing components.

Class **Component** (package `java.awt`) is a superclass that declares the common features of GUI components in packages `java.awt` and `javax.swing`. Any object that is a **Container** (package `java.awt`) can be used to organize Components by attaching the Components to the Container. Containers can be placed in other Containers to organize a GUI.

Class **JComponent** (package `javax.swing`) is a subclass of **Container**. **JComponent** is the superclass of all lightweight Swing components and declares their common attributes and behaviors. Because **JComponent** is a subclass of **Container**, all lightweight Swing components are also Containers. Some common features supported by **JComponent** include:

1. A **pluggable look-and-feel** for customizing the appearance of components (e.g., for use on particular platforms). You'll see an example of this in Section 25.6.
2. Shortcut keys (called **mnemonics**) for direct access to GUI components through the keyboard. You'll see an example of this in Section 25.4.
3. Brief descriptions of a GUI component's purpose (called **tool tips**) that are displayed when the mouse cursor is positioned over the component for a short time. You'll see an example of this in the next section.
4. Support for accessibility, such as braille screen readers for the visually impaired.
5. Support for user-interface **localization**—that is, customizing the user interface to display in different languages and use local cultural conventions.

## 14.5 Displaying Text and Images in a Window

Our next example introduces a framework for building GUI applications. Several concepts in this framework will appear in many of our GUI applications. This is our first example in which the application appears in its own window. Most windows you'll create that can contain Swing GUI components are instances of class `JFrame` or a subclass of `JFrame`. `JFrame` is an indirect subclass of class `java.awt.Window` that provides the basic attributes and behaviors of a window—a title bar at the top, and buttons to minimize, maximize and close the window. Since an application's GUI is typically specific to the application, most of our examples will consist of two classes—a subclass of `JFrame` that helps us demonstrate new GUI concepts and an application class in which `main` creates and displays the application's primary window.

### Labeling GUI Components

A typical GUI consists of many components. GUI designers often provide text stating the purpose of each. Such text is known as a **label** and is created with a `JLabel`—a subclass of `JComponent`. A `JLabel` displays read-only text, an image, or both text and an image. Applications rarely change a label's contents after creating it.

#### Look-and-Feel Observation 14.6

*Text in a `JLabel` normally uses sentence-style capitalization.*

The application of Figs. 14.6–14.7 demonstrates several `JLabel` features and presents the framework we use in most of our GUI examples. We did not highlight the code in this example, since most of it is new. [Note: There are many more features for each GUI component than we can cover in our examples. To learn the complete details of each GUI component, visit its page in the online documentation. For class `JLabel`, visit [download.oracle.com/javase/6/docs/api/javaw/swing/JLabel.html](http://download.oracle.com/javase/6/docs/api/javaw/swing/JLabel.html).]

```

1 // Fig. 14.6: LabelFrame.java
2 // Demonstrating the JLabel class.
3 import java.awt.FlowLayout; // specifies how components are arranged
4 import javax.swing.JFrame; // provides basic window features
5 import javax.swing.JLabel; // displays text and images
6 import javax.swing.SwingConstants; // common constants used with Swing
7 import javax.swing.Icon; // interface used to manipulate images
8 import javax.swing.ImageIcon; // loads images
9
10 public class LabelFrame extends JFrame
11 {
12     private JLabel label1; // JLabel with just text
13     private JLabel label2; // JLabel constructed with text and icon
14     private JLabel label3; // JLabel with added text and icon
15
16     // LabelFrame constructor adds JLabels to JFrame
17     public LabelFrame()
18     {

```

**Fig. 14.6** | `JLabel`s with text and icons. (Part 1 of 2.)

```

19     super( "Testing JLabel" );
20     setLayout( new FlowLayout() ); // set frame layout
21
22     // JLabel constructor with a string argument
23     label1 = new JLabel( "Label with text" );
24     label1.setToolTipText( "This is label1" );
25     add( label1 ); // add label1 to JFrame
26
27     // JLabel constructor with string, Icon and alignment arguments
28     Icon bug = new ImageIcon( getClass().getResource( "bug1.png" ) );
29     label2 = new JLabel( "Label with text and icon", bug,
30         SwingConstants.LEFT );
31     label2.setToolTipText( "This is label2" );
32     add( label2 ); // add label2 to JFrame
33
34     label3 = new JLabel(); // JLabel constructor no arguments
35     label3.setText( "Label with icon and text at bottom" );
36     label3.setIcon( bug ); // add icon to JLabel
37     label3.setHorizontalTextPosition( SwingConstants.CENTER );
38     label3.setVerticalTextPosition( SwingConstants.BOTTOM );
39     label3.setToolTipText( "This is label3" );
40     add( label3 ); // add label3 to JFrame
41 } // end LabelFrame constructor
42 } // end class LabelFrame

```

**Fig. 14.6** | JLabels with text and icons. (Part 2 of 2.)

```

1 // Fig. 14.7: LabelTest.java
2 // Testing LabelFrame.
3 import javax.swing.JFrame;
4
5 public class LabelTest
6 {
7     public static void main( String[] args )
8     {
9         LabelFrame labelFrame = new LabelFrame(); // create LabelFrame
10        labelFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        labelFrame.setSize( 260, 180 ); // set frame size
12        labelFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class LabelTest

```

**Fig. 14.7** | Test class for LabelFrame.

Class `LabelFrame` (Fig. 14.6) is a subclass of `JFrame`. We'll use an instance of class `LabelFrame` to display a window containing three `JLabels`. Lines 3–8 import the classes used in class `LabelFrame`. The class extends `JFrame` to inherit the features of a window. Lines 12–14 declare the three `JLabel` instance variables that are instantiated in the `LabelFrame` constructor (lines 17–41). Typically, the `JFrame` subclass's constructor builds the GUI that's displayed in the window when the application executes. Line 19 invokes superclass `JFrame`'s constructor with the argument `"Testing JLabel"`. `JFrame`'s constructor uses this `String` as the text in the window's title bar.

### Specifying the Layout

When building a GUI, you must attach each GUI component to a container, such as a window created with a `JFrame`. Also, you typically must decide *where* to position each GUI component—known as specifying the layout. Java provides several **layout managers** that can help you position components, as you'll learn at the end of this chapter and in Chapter 25.

Many IDEs provide GUI design tools in which you can specify components' exact sizes and locations in a visual manner by using the mouse; then the IDE will generate the GUI code for you. Such IDEs can greatly simplify GUI creation.

To ensure that our GUIs can be used with *any* IDE, we did *not* use an IDE to create the GUI code. We use Java's layout managers to size and position components. With the **FlowLayout** layout manager, components are placed on a container from left to right in the order in which they're added. When no more components can fit on the current line, they continue to display left to right on the next line. If the container is resized, a `FlowLayout` *reflows* the components, possibly with fewer or more rows based on the new container width. Every container has a default layout, which we're changing for `LabelFrame` to a `FlowLayout` (line 20). Method **setLayout** is inherited into class `LabelFrame` indirectly from class `Container`. The argument to the method must be an object of a class that implements the `LayoutManager` interface (e.g., `FlowLayout`). Line 20 creates a new `FlowLayout` object and passes its reference as the argument to `setLayout`.

### Creating and Attaching `Label1`

Now that we've specified the window's layout, we can begin creating and attaching GUI components to the window. Line 23 creates a `JLabel` object and passes `"Label with text"` to the constructor. The `JLabel` displays this text on the screen as part of the application's GUI. Line 24 uses method **setToolTipText** (inherited by `JLabel` from `JComponent`) to specify the tool tip that's displayed when the user positions the mouse cursor over the `JLabel` in the GUI. You can see a sample tool tip in the second screen capture of Fig. 14.7. When you execute this application, try positioning the mouse over each `JLabel` to see its tool tip. Line 25 attaches `label1` to the `LabelFrame` by passing `label1` to the **add** method, which is inherited indirectly from class `Container`.

#### Common Programming Error 14.1

*If you do not explicitly add a GUI component to a container, the GUI component will not be displayed when the container appears on the screen.*

#### Look-and-Feel Observation 14.7

*Use tool tips to add descriptive text to your GUI components. This text helps the user determine the GUI component's purpose in the user interface.*

### *The Icon Interface and Class ImageIcon*

Icons are a popular way to enhance the look-and-feel of an application and are also commonly used to indicate functionality. For example, the same icon is used to play most of today's media on devices like DVD players and MP3 players. Several Swing components can display images. An icon is normally specified with an **Icon** argument to a constructor or to the component's **setIcon** method. An **Icon** is an object of any class that implements interface **Icon** (package `javax.swing`). Class **ImageIcon** supports several image formats, including Graphics Interchange Format (GIF), Portable Network Graphics (PNG) and Joint Photographic Experts Group (JPEG).

Line 28 declares an **ImageIcon**. The file `bug1.png` contains the image to load and store in the **ImageIcon** object. This image is included in the directory for this example. The **ImageIcon** object is assigned to **Icon** reference `bug`.

### *Loading an Image Resource*

In line 28, the expression `getClass().getResource("bug1.png")` invokes method **getResource** (inherited indirectly from class **Object**) to retrieve a reference to the **Class** object that represents the `LabelFrame` class declaration. That reference is then used to invoke **Class** method **getResource**, which returns the location of the image as a URL. The **ImageIcon** constructor uses the URL to locate the image, then loads it into memory. As we discussed in Chapter 1, the JVM loads class declarations into memory, using a class loader. The class loader knows where each class it loads is located on disk. Method **getResource** uses the **Class** object's class loader to determine the location of a resource, such as an image file. In this example, the image file is stored in the same location as the `LabelFrame.class` file. The techniques described here enable an application to load image files from locations that are relative to the class file's location.

### *Creating and Attaching label2*

Lines 29–30 use another **JLabel** constructor to create a **JLabel** that displays the text "Label with text and icon" and the **Icon** `bug` created in line 28. The last constructor argument indicates that the label's contents are left justified, or left aligned (i.e., the icon and text are at the left side of the label's area on the screen). Interface **SwingConstants** (package `javax.swing`) declares a set of common integer constants (such as `SwingConstants.LEFT`) that are used with many Swing components. By default, the text appears to the right of the image when a label contains both text and an image. The horizontal and vertical alignments of a **JLabel** can be set with methods **setHorizontalAlignment** and **setVerticalAlignment**, respectively. Line 31 specifies the tool-tip text for `label2`, and line 32 adds `label2` to the **JFrame**.

### *Creating and Attaching label3*

Class **JLabel** provides methods to change a label's appearance after it's been instantiated. Line 34 creates an empty **JLabel** with the no-argument constructor. Line 35 uses **JLabel** method **setText** to set the text displayed on the label. Method **getText** can be used to retrieve the current text displayed on a label. Line 36 uses **JLabel** method **setIcon** to specify the **Icon** to display on the label. Method **getIcon** can be used to retrieve the current **Icon** displayed on a label. Lines 37–38 use **JLabel** methods **setHorizontalTextPosition** and **setVerticalTextPosition** to specify the text position in the label. In this case, the text will be centered horizontally and will appear at the bottom of the label. Thus, the **Icon**

will appear above the text. The horizontal-position constants in `SwingConstants` are `LEFT`, `CENTER` and `RIGHT` (Fig. 14.8). The vertical-position constants in `SwingConstants` are `TOP`, `CENTER` and `BOTTOM` (Fig. 14.8). Line 39 sets the tool-tip text for `label3`. Line 40 adds `label3` to the `JFrame`.

| Constant                             | Description              | Constant                           | Description              |
|--------------------------------------|--------------------------|------------------------------------|--------------------------|
| <i>Horizontal-position constants</i> |                          | <i>Vertical-position constants</i> |                          |
| <code>LEFT</code>                    | Place text on the left   | <code>TOP</code>                   | Place text at the top    |
| <code>CENTER</code>                  | Place text in the center | <code>CENTER</code>                | Place text in the center |
| <code>RIGHT</code>                   | Place text on the right  | <code>BOTTOM</code>                | Place text at the bottom |

**Fig. 14.8** | Positioning constants (static members of interface `SwingConstants`).

### *Creating and Displaying a `LabelFrame` Window*

Class `LabelTest` (Fig. 14.7) creates an object of class `LabelFrame` (line 9), then specifies the default close operation for the window. By default, closing a window simply hides the window. However, when the user closes the `LabelFrame` window, we would like the application to terminate. Line 10 invokes `LabelFrame`'s `setDefaultCloseOperation` method (inherited from class `JFrame`) with constant `JFrame.EXIT_ON_CLOSE` as the argument to indicate that the program should terminate when the window is closed by the user. This line is important. Without it the application will not terminate when the user closes the window. Next, line 11 invokes `LabelFrame`'s `setSize` method to specify the width and height of the window in pixels. Finally, line 12 invokes `LabelFrame`'s `setVisible` method with the argument `true` to display the window on the screen. Try resizing the window to see how the `FlowLayout` changes the `JLabel` positions as the window width changes.

## 14.6 Text Fields and an Introduction to Event Handling with Nested Classes

Normally, a user interacts with an application's GUI to indicate the tasks that the application should perform. For example, when you write an e-mail in an e-mail application, clicking the **Send** button tells the application to send the e-mail to the specified e-mail addresses. GUIs are **event driven**. When the user interacts with a GUI component, the interaction—known as an **event**—drives the program to perform a task. Some common user interactions that cause an application to perform a task include clicking a button, typing in a text field, selecting an item from a menu, closing a window and moving the mouse. The code that performs a task in response to an event is called an **event handler**, and the overall process of responding to events is known as **event handling**.

Let's consider two other GUI components that can generate events—**`JTextField`**s and **`JPasswordField`**s (package `javax.swing`). Class `JTextField` extends class **`JTextComponent`** (package `javax.swing.text`), which provides many features common to Swing's text-based components. Class `JPasswordField` extends `JTextField` and adds methods that are specific to processing passwords. Each of these components is a single-line area in which the user can enter text via the keyboard. Applications can also display text in a `JTextField` (see the output of Fig. 14.10). A `JPasswordField` shows that characters are

being typed as the user enters them, but hides the actual characters with an **echo character**, assuming that they represent a password that should remain known only to the user.

When the user types in a `JTextField` or a `JPasswordField`, then presses *Enter*, an event occurs. Our next example demonstrates how a program can perform a task in response to that event. The techniques shown here are applicable to all GUI components that generate events.

The application of Figs. 14.9–14.10 uses classes `JTextField` and `JPasswordField` to create and manipulate four text fields. When the user types in one of the text fields, then presses *Enter*, the application displays a message dialog box containing the text the user typed. You can type only in the text field that’s “in **focus**.” When you click a component, it *receives the focus*. This is important, because the text field with the focus is the one that generates an event when you press *Enter*. In this example, you press *Enter* in the `JPasswordField`, the password is revealed. We begin by discussing the setup of the GUI, then discuss the event-handling code.

Lines 3–9 import the classes and interfaces we use in this example. Class `TextFieldFrame` extends `JFrame` and declares three `JTextField` variables and a `JPasswordField` variable (lines 13–16). Each of the corresponding text fields is instantiated and attached to the `TextFieldFrame` in the constructor (lines 19–47).

54     {
55         String string = ""; // declare string to display
56
57         // user pressed Enter in JTextField textField1
58         if ( event.getSource() == textField1 )
59             string = String.format( "textField1: %s",
60                                     event.getActionCommand() );
61
62         // user pressed Enter in JTextField textField2
63         else if ( event.getSource() == textField2 )
64             string = String.format( "textField2: %s",
65                                     event.getActionCommand() );
66
67         // user pressed Enter in JTextField textField3
68         else if ( event.getSource() == textField3 )
69             string = String.format( "textField3: %s",
70                                     event.getActionCommand() );
71
72         // user pressed Enter in JTextField passwordField
73         else if ( event.getSource() == passwordField )
74             string = String.format( "passwordField: %s",
75                                     event.getActionCommand() );
76
77         // display JTextField content
78         JOptionPane.showMessageDialog( null, string );
79     } // end method actionPerformed
80 } // end private inner class TextFieldHandler
81 } // end class TextFieldFrame
```

**Fig. 14.9** | JTextFields and JPasswordField. (Part 2 of 2.)

### Creating the GUI

Line 22 sets the `TextField`'s layout to `FlowLayout`. Line 25 creates `textField1` with 10 columns of text. A text column's width in *pixels* is determined by the average width of a character in the text field's current font. When text is displayed in a text field and the text is wider than the field itself, a portion of the text at the right side is not visible. If you're typing in a text field and the cursor reaches the right edge, the text at the left edge is pushed off the left side of the field and is no longer visible. Users can use the left and right arrow keys to move through the complete text. Line 26 adds `textField1` to the `JFrame`.

Line 29 creates `textField2` with the initial text "Enter text here" to display in the text field. The width of the field is determined by the width of the default text specified in the constructor. Line 30 adds `textField2` to the `JFrame`.

Line 33 creates `textField3` and calls the `JTextField` constructor with two arguments—the default text "Uneditable text field" to display and the text field's width in columns (21). Line 34 uses method `setEditable` (inherited by `JTextField` from class `JTextComponent`) to make the text field *uneditable*—i.e., the user cannot modify the text in the field. Line 35 adds `textField3` to the `JFrame`.

Line 38 creates `passwordField` with the text "Hidden text" to display in the text field. The width of the field is determined by the width of the default text. When you execute the application, notice that the text is displayed as a string of asterisks. Line 39 adds `passwordField` to the `JFrame`.

### Steps Required to Set Up Event Handling for a GUI Component

This example should display a message dialog containing the text from a text field when the user presses *Enter* in that text field. Before an application can respond to an event for a particular GUI component, you must:

1. Create a class that represents the event handler and implements an appropriate interface—known as an **event-listener interface**.
2. Indicate that an object of the class from *Step 1* should be notified when the event occurs—known as **registering the event handler**.

### Using a Nested Class to Implement an Event Handler

All the classes discussed so far were so-called **top-level classes**—that is, they were not declared inside another class. Java allows you to declare classes *inside* other classes—these are called **nested classes**. Nested classes can be *static* or *non-static*. *Non-static* nested classes are called **inner classes** and are frequently used to implement *event handlers*.

An inner-class object must be created by an object of the top-level class that contains the inner class. Each inner-class object *implicitly* has a reference to an object of its top-level class. The inner-class object is allowed to use this implicit reference to directly access all the variables and methods of the top-level class. A nested class that's *static* does not require an object of its top-level class and does not implicitly have a reference to an object of the top-level class. As you'll see in Chapter 15, Graphics and Java 2D, the Java 2D graphics API uses *static* nested classes extensively.

### Inner Class `TextFieldHandler`

The event handling in this example is performed by an object of the private inner class `TextFieldHandler` (lines 50–80). This class is *private* because it will be used only to cre-

ate event handlers for the text fields in top-level class `TextFieldFrame`. As with other class members, *inner classes* can be declared `public`, `protected` or `private`. Since event handlers tend to be specific to the application in which they're defined, they're often implemented as `private` inner classes or as *anonymous inner classes* (Section 14.11).

GUI components can generate many events in response to user interactions. Each event is represented by a class and can be processed only by the appropriate type of event handler. Normally, a component's supported events are described in the Java API documentation for that component's class and its superclasses. When the user presses *Enter* in a `JTextField` or `JPasswordField`, an **ActionEvent** (package `java.awt.event`) occurs. Such an event is processed by an object that implements the interface **ActionListener** (package `java.awt.event`). The information discussed here is available in the Java API documentation for classes `JTextField` and `ActionEvent`. Since `JPasswordField` is a subclass of `JTextField`, `JPasswordField` supports the same events.

To prepare to handle the events in this example, inner class `TextFieldHandler` implements interface `ActionListener` and declares the only method in that interface—`actionPerformed` (lines 53–79). This method specifies the tasks to perform when an `ActionEvent` occurs. So, inner class `TextFieldHandler` satisfies *Step 1* listed earlier in this section. We'll discuss the details of method `actionPerformed` shortly.

### Registering the Event Handler for Each Text Field

In the `TextFieldFrame` constructor, line 42 creates a `TextFieldHandler` object and assigns it to variable `handler`. This object's `actionPerformed` method will be called automatically when the user presses *Enter* in any of the GUI's text fields. However, before this can occur, the program must register this object as the event handler for each text field. Lines 43–46 are the event-registration statements that specify `handler` as the event handler for the three `JTextFields` and the `JPasswordField`. The application calls `JTextField` method `addActionListener` to register the event handler for each component. This method receives as its argument an `ActionListener` object, which can be an object of any class that implements `ActionListener`. The object `handler` is an `ActionListener`, because class `TextFieldHandler` implements `ActionListener`. After lines 43–46 execute, the object `handler` **listens for events**. Now, when the user presses *Enter* in any of these four text fields, method `actionPerformed` (line 53–79) in class `TextFieldHandler` is called to handle the event. If an event handler is not registered for a particular text field, the event that occurs when the user presses *Enter* in that text field is **consumed**—i.e., it's simply ignored by the application.

#### Software Engineering Observation 14.1

The event listener for an event must implement the appropriate event-listener interface.

#### Common Programming Error 14.2

Forgetting to register an event-handler object for a particular GUI component's event type causes events of that type to be ignored.

### Details of Class `TextFieldHandler`'s `actionPerformed` Method

In this example, we're using one event-handling object's `actionPerformed` method (lines 53–79) to handle the events generated by four text fields. Since we'd like to output the

name of each text field's instance variable for demonstration purposes, we must determine which text field generated the event each time `actionPerformed` is called. The **event source** is the GUI component with which the user interacted. When the user presses *Enter* while one of the text fields or the password field *has the focus*, the system creates a unique `ActionEvent` object that contains information about the event that just occurred, such as the event source and the text in the text field. The system passes this `ActionEvent` object to the event listener's `actionPerformed` method. Line 55 declares the `String` that will be displayed. The variable is initialized with the **empty string**—a `String` containing no characters. The compiler requires the variable to be initialized in case none of the branches of the nested `if` in lines 58–75 executes.

`ActionEvent` method `getSource` (called in lines 58, 63, 68 and 73) returns a reference to the event source. The condition in line 58 asks, “Is the event source `textField1`?” This condition compares references with the `==` operator to determine if they refer to the same object. If they *both* refer to `textField1`, the user pressed *Enter* in `textField1`. Then, lines 59–60 create a `String` containing the message that line 78 displays in a message dialog. Line 60 uses `ActionEvent` method **`getActionCommand`** to obtain the text the user typed in the text field that generated the event.

In this example, we display the text of the password in the `JPasswordField` when the user presses *Enter* in that field. Sometimes it's necessary to programmatically process the characters in a password. Class `JPasswordField` method **`getPassword`** returns the password's characters as an array of type `char`.

### Class `TextFieldTest`

Class `TextFieldTest` (Fig. 14.10) contains the `main` method that executes this application and displays an object of class `TextFieldFrame`. When you execute the application, even the uneditable `JTextField` (`textField3`) can generate an `ActionEvent`. To test this, click the text field to give it the focus, then press *Enter*. Also, the actual text of the password is displayed when you press *Enter* in the `JPasswordField`. Of course, you would normally not display the password!

This application used a single object of class `TextFieldHandler` as the event listener for four text fields. Starting in Section 14.10, you'll see that it's possible to declare several event-listener objects of the same type and register each object for a separate GUI component's event. This technique enables us to eliminate the `if...else` logic used in this example's event handler by providing separate event handlers for each component's events.

## 14.7 Common GUI Event Types and Listener Interfaces

In Section 14.6, you learned that information about the event that occurs when the user presses *Enter* in a text field is stored in an `ActionEvent` object. Many different types of events can occur when the user interacts with a GUI. The event information is stored in an object of a class that extends `AWTEvent` (from package `java.awt`). Figure 14.11 illustrates a hierarchy containing many event classes from the package `java.awt.event`. Some of these are discussed in this chapter and Chapter 25. These event types are used with both AWT and Swing components. Additional event types that are specific to Swing GUI components are declared in package `javax.swing.event`.

Let's summarize the three parts to the event-handling mechanism that you saw in Section 14.6—the *event source*, the *event object* and the *event listener*. The event source is

**Fig. 14.11** | Some event classes of package `java.awt.event`.

the GUI component with which the user interacts. The event object encapsulates information about the event that occurred, such as a reference to the event source and any event-specific information that may be required by the event listener for it to handle the event. The event listener is an object that's notified by the event source when an event occurs; in effect, it “listens” for an event, and one of its methods executes in response to the event. A method of the event listener receives an event object when the event listener is notified of the event. The event listener then uses the event object to respond to the event. This event-handling model is known as the **delegation event model**—an event's processing is delegated to an object (the event listener) in the application.

For each event-object type, there's typically a corresponding event-listener interface. An event listener for a GUI event is an object of a class that implements one or more of the event-listener interfaces from packages `java.awt.event` and `javax.swing.event`. Many of the event-listener types are common to both Swing and AWT components. Such types are declared in package `java.awt.event`, and some of them are shown in Fig. 14.12. Additional event-listener types that are specific to Swing components are declared in package `javax.swing.event`.

Each event-listener interface specifies one or more event-handling methods that *must* be declared in the class that implements the interface. Recall from Section 10.7 that any class which implements an interface must declare *all* the abstract methods of that interface; otherwise, the class is an abstract class and cannot be used to create objects.

**Fig. 14.12** | Some common event-listener interfaces of package `java.awt.event`.

When an event occurs, the GUI component with which the user interacted notifies its *registered listeners* by calling each listener’s appropriate *event-handling method*. For example, when the user presses the *Enter* key in a `JTextField`, the registered listener’s `actionPerformed` method is called. How did the event handler get registered? How does the GUI component know to call `actionPerformed` rather than another event-handling method? We answer these questions and diagram the interaction in the next section.

## 14.8 How Event Handling Works

Let’s illustrate how the event-handling mechanism works, using `textField1` from the example of Fig. 14.9. We have two remaining open questions from Section 14.7:

1. How did the *event handler* get *registered*?
2. How does the GUI component know to call `actionPerformed` rather than some other event-handling method?

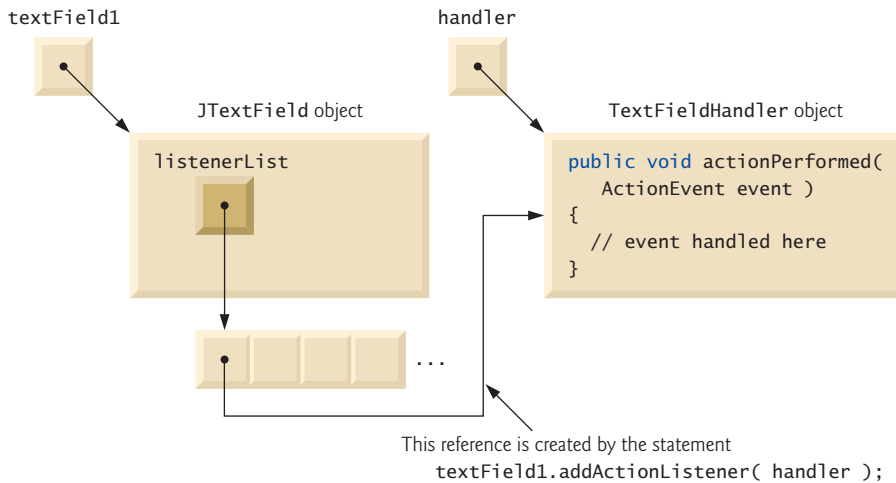

The first question is answered by the event registration performed in lines 43–46 of Fig. 14.9. Figure 14.13 diagrams `JTextField` variable `textField1`, `TextFieldHandler` variable `handler` and the objects to which they refer.

### Registering Events

Every `JComponent` has an instance variable called `listenerList` that refers to an object of class `EventListenerList` (package `javax.swing.event`). Each object of a `JComponent` subclass maintains references to its registered listeners in the `listenerList`. For simplicity, we’ve diagrammed `listenerList` as an array below the `JTextField` object in Fig. 14.13.

When line 43 of Fig. 14.9

```
textField1.addActionListener( handler );
```

**Fig. 14.13** | Event registration for `JTextField` `textField1`.

executes, a new entry containing a reference to the `TextFieldHandler` object is placed in `textField1`'s `listenerList`. Although not shown in the diagram, this new entry also includes the listener's type (in this case, `ActionListener`). Using this mechanism, each lightweight Swing GUI component maintains its own list of *listeners* that were *registered* to *handle* the component's *events*.

### Event-Handler Invocation

The event-listener type is important in answering the second question: How does the GUI component know to call `actionPerformed` rather than another method? Every GUI component supports several *event types*, including **mouse events**, **key events** and others. When an event occurs, the event is **dispatched** only to the *event listeners* of the appropriate type. Dispatching is simply the process by which the GUI component calls an event-handling method on each of its listeners that are registered for the event type that occurred.

Each *event type* has one or more corresponding *event-listener interfaces*. For example, `ActionEvents` are handled by `ActionListeners`, **MouseEvents** by **MouseListeners** and **MouseMotionListeners**, and **KeyEvents** by **KeyListeners**. When an event occurs, the GUI component receives (from the JVM) a unique *event ID* specifying the event type. The GUI component uses the event ID to decide the listener type to which the event should be dispatched and to decide which method to call on each listener object. For an `ActionEvent`, the event is dispatched to *every* registered `ActionListener`'s `actionPerformed` method (the only method in interface `ActionListener`). For a `MouseEvent`, the event is dispatched to *every* registered `MouseListener` or `MouseMotionListener`, depending on the mouse event that occurs. The `MouseEvent`'s event ID determines which of the several mouse event-handling methods are called. All these decisions are handled for you by the GUI components. All you need to do is register an event handler for the particular event type that your application requires, and the GUI component will ensure that the event handler's appropriate method gets called when the event occurs. We discuss

other event types and event-listener interfaces as they're needed with each new component we introduce.

## 14.9 JButton

A **button** is a component the user clicks to trigger a specific action. A Java application can use several types of buttons, including **command buttons**, **checkboxes**, **toggle buttons** and **radio buttons**. Figure 14.14 shows the inheritance hierarchy of the Swing buttons we cover in this chapter. As you can see, all the button types are subclasses of **AbstractButton** (package `javax.swing`), which declares the common features of Swing buttons. In this section, we concentrate on buttons that are typically used to initiate a command.

**Fig. 14.14** | Swing button hierarchy.

A command button (see Fig. 14.16's output) generates an `ActionEvent` when the user clicks it. Command buttons are created with class **JButton**. The text on the face of a `JButton` is called a **button label**. A GUI can have many `JButtons`, but each button label should be unique in the portion of the GUI that's currently displayed.

### Look-and-Feel Observation 14.8

*The text on buttons typically uses book-title capitalization.*

### Look-and-Feel Observation 14.9

*Having more than one `JButton` with the same label makes the `JButtons` ambiguous to the user. Provide a unique label for each button.*

The application of Figs. 14.15 and 14.16 creates two `JButtons` and demonstrates that `JButtons` support the display of `Icons`. Event handling for the buttons is performed by a single instance of *inner class* `ButtonHandler` (lines 39–47).

Lines 14–15 declare `JButton` variables `plainJButton` and `fancyJButton`. The corresponding objects are instantiated in the constructor. Line 23 creates `plainJButton` with the button label "Plain Button". Line 24 adds the `JButton` to the `JFrame`.

A `JButton` can display an `Icon`. To provide the user with an extra level of visual interaction with the GUI, a `JButton` can also have a **rollover `Icon`**—an `Icon` that's displayed

```

10 import javax.swing.JOptionPane;
11
12 public class ButtonFrame extends JFrame
13 {
14     private JButton plainJButton; // button with just text
15     private JButton fancyJButton; // button with icons
16
17     // ButtonFrame adds JButtons to JFrame
18     public ButtonFrame()
19     {
20         super( "Testing Buttons" );
21         setLayout( new FlowLayout() ); // set frame layout
22
23         plainJButton = new JButton( "Plain Button" ); // button with text
24         add( plainJButton ); // add plainJButton to JFrame
25
26         Icon bug1 = new ImageIcon( getClass().getResource( "bug1.gif" ) );
27         Icon bug2 = new ImageIcon( getClass().getResource( "bug2.gif" ) );
28         fancyJButton = new JButton( "Fancy Button", bug1 ); // set image
29         fancyJButton.setRolloverIcon( bug2 ); // set rollover image
30         add( fancyJButton ); // add fancyJButton to JFrame
31
32         // create new ButtonHandler for button event handling
33         ButtonHandler handler = new ButtonHandler();
34         fancyJButton.addActionListener( handler );
35         plainJButton.addActionListener( handler );
36     } // end ButtonFrame constructor
37
38     // inner class for button event handling
39     private class ButtonHandler implements ActionListener
40     {
41         // handle button event
42         public void actionPerformed( ActionEvent event )
43         {
44             JOptionPane.showMessageDialog( ButtonFrame.this, String.format(
45                 "You pressed: %s", event.getActionCommand() ) );
46         } // end method actionPerformed
47     } // end private inner class ButtonHandler
48 } // end class ButtonFrame

```

**Fig. 14.15** | Command buttons and action events.

when the user positions the mouse over the JButton. The icon on the JButton changes as the mouse moves in and out of the JButton's area on the screen. Lines 26–27 (Fig. 14.15) create two ImageIcon objects that represent the default Icon and rollover Icon for the

```

1 // Fig. 14.16: ButtonTest.java
2 // Testing ButtonFrame.
3 import javax.swing.JFrame;
4
5 public class ButtonTest
6 {
7     public static void main( String[] args )
8     {
9         ButtonFrame buttonFrame = new ButtonFrame(); // create ButtonFrame
10        buttonFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        buttonFrame.setSize( 275, 110 ); // set frame size
12        buttonFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class ButtonTest

```

**Fig. 14.16** | Test class for ButtonFrame.

JButton created at line 28. Both statements assume that the image files are stored in the same directory as the application. Images are commonly placed in the same directory as the application or a subdirectory like `images`). These image files have been provided for you with the example.

Line 28 creates `fancyButton` with the text "Fancy Button" and the icon `bug1`. By default, the text is displayed to the right of the icon. Line 29 uses `setRollOverIcon` (inherited from class `AbstractButton`) to specify the image displayed on the JButton when the user positions the mouse over it. Line 30 adds the JButton to the JFrame.

### Look-and-Feel Observation 14.10

Because class `AbstractButton` supports displaying text and images on a button, all subclasses of `AbstractButton` also support displaying text and images.

### Look-and-Feel Observation 14.11

Using rollover icons for `JButtons` provides users with visual feedback indicating that when they click the mouse while the cursor is positioned over the `JButton`, an action will occur.

`JButtons`, like `JTextFields`, generate `ActionEvents` that can be processed by any `ActionListener` object. Lines 33–35 create an object of private *inner class* `ButtonHandler` and use `addActionListener` to register it as the *event handler* for each `JButton`. Class `ButtonHandler` (lines 39–47) declares `actionPerformed` to display a message dialog box containing the label for the button the user pressed. For a `JButton` event, `ActionEvent` method `getActionCommand` returns the label on the `JButton`.

### Accessing the `this` Reference in an Object of a Top-Level Class From an Inner Class

When you execute this application and click one of its buttons, notice that the message dialog that appears is centered over the application's window. This occurs because the call to `JOptionPane` method `showMessageDialog` (lines 44–45 of Fig. 14.15) uses `ButtonFrame.this` rather than `null` as the first argument. When this argument is not `null`, it represents the so-called *parent GUI component* of the message dialog (in this case the application window is the parent component) and enables the dialog to be centered over that component when the dialog is displayed. `ButtonFrame.this` represents the `this` reference of the object of top-level class `ButtonFrame`.

### Software Engineering Observation 14.2

When used in an inner class, keyword `this` refers to the current inner-class object being manipulated. An inner-class method can use its outer-class object's `this` by preceding `this` with the outer-class name and a dot, as in `ButtonFrame.this`.

## 14.10 Buttons That Maintain State

The Swing GUI components contain three types of **state buttons**—`JToggleButton`, `JCheckBox` and `JRadioButton`—that have on/off or true/false values. Classes `JCheckBox` and `JRadioButton` are subclasses of `JToggleButton` (Fig. 14.14). A `JRadioButton` is different from a `JCheckBox` in that normally several `JRadioButtons` are grouped together and are mutually exclusive—only one in the group can be selected at any time, just like the buttons on a car radio. We first discuss class `JCheckBox`.

### 14.10.1 `JCheckBox`

The application of Figs. 14.17–14.18 uses two `JCheckBoxes` to select the desired font style of the text displayed in a `JTextField`. When selected, one applies a bold style and the other an italic style. If *both* are selected, the style is bold and italic. When the application initially executes, neither `JCheckBox` is checked (i.e., they're both `false`), so the font is plain. Class `CheckBoxTest` (Fig. 14.18) contains the main method that executes this application.

```

1 // Fig. 14.17: CheckBoxFrame.java
2 // Creating JCheckBox buttons.
3 import java.awt.FlowLayout;
4 import java.awt.Font;
5 import java.awt.event.ItemListener;
6 import java.awt.event.ItemEvent;
7 import javax.swing.JFrame;
8 import javax.swing.JTextField;
9 import javax.swing.JCheckBox;
10
11 public class CheckBoxFrame extends JFrame
12 {
13     private JTextField textField; // displays text in changing fonts
14     private JCheckBox boldJCheckBox; // to select/deselect bold
15     private JCheckBox italicJCheckBox; // to select/deselect italic
16
17     // CheckBoxFrame constructor adds JCheckBoxes to JFrame
18     public CheckBoxFrame()
19     {
20         super( "JCheckBox Test" );
21         setLayout( new FlowLayout() ); // set frame layout
22
23         // set up JTextField and set its font
24         textField = new JTextField( "Watch the font style change", 20 );
25         textField.setFont( new Font( "Serif", Font.PLAIN, 14 ) );
26         add( textField ); // add textField to JFrame
27
28         boldJCheckBox = new JCheckBox( "Bold" ); // create bold checkbox
29         italicJCheckBox = new JCheckBox( "Italic" ); // create italic
30         add( boldJCheckBox ); // add bold checkbox to JFrame
31         add( italicJCheckBox ); // add italic checkbox to JFrame
32
33         // register listeners for JCheckBoxes
34         CheckBoxHandler handler = new CheckBoxHandler();
35         boldJCheckBox.addItemListener( handler );
36         italicJCheckBox.addItemListener( handler );
37     } // end CheckBoxFrame constructor
38
39     // private inner class for ItemListener event handling
40     private class CheckBoxHandler implements ItemListener
41     {
42         // respond to checkbox events
43         public void itemStateChanged( ItemEvent event )
44         {
45             Font font = null; // stores the new Font
46
47             // determine which CheckBoxes are checked and create Font
48             if ( boldJCheckBox.isSelected() && italicJCheckBox.isSelected() )
49                 font = new Font( "Serif", Font.BOLD + Font.ITALIC, 14 );
50             else if ( boldJCheckBox.isSelected() )
51                 font = new Font( "Serif", Font.BOLD, 14 );
52             else if ( italicJCheckBox.isSelected() )
53                 font = new Font( "Serif", Font.ITALIC, 14 );

```

**Fig. 14.17** | JCheckBox buttons and item events. (Part 1 of 2.)

```

54         else
55             font = new Font( "Serif", Font.PLAIN, 14 );
56
57             textField.setFont( font ); // set textField's font
58         } // end method itemStateChanged
59     } // end private inner class CheckBoxHandler
60 } // end class CheckBoxFrame

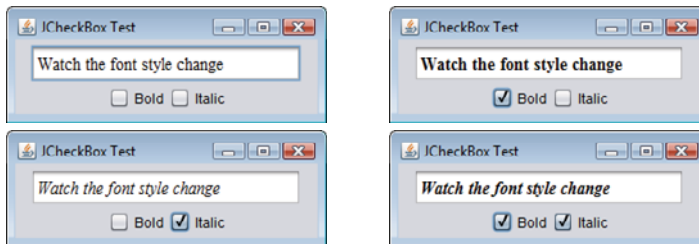

```

**Fig. 14.17** | JCheckBox buttons and item events. (Part 2 of 2.)

```

1 // Fig. 14.18: CheckBoxTest.java
2 // Testing CheckBoxFrame.
3 import javax.swing.JFrame;
4
5 public class CheckBoxTest
6 {
7     public static void main( String[] args )
8     {
9         CheckBoxFrame checkBoxFrame = new CheckBoxFrame();
10        checkBoxFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        checkBoxFrame.setSize( 275, 100 ); // set frame size
12        checkBoxFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class CheckBoxTest

```

**Fig. 14.18** | Test class for CheckBoxFrame.

After the `JTextField` is created and initialized (Fig. 14.17, line 24), line 25 uses method `setFont` (inherited by `JTextField` indirectly from class `Component`) to set the font of the `JTextField` to a new object of class `Font` (package `java.awt`). The new `Font` is initialized with "Serif" (a generic font name that represents a font such as Times and is supported on all Java platforms), `Font.PLAIN` style and 14-point size. Next, lines 28–29 create two `JCheckBox` objects. The `String` passed to the `JCheckBox` constructor is the **checkbox label** that appears to the right of the `JCheckBox` by default.

When the user clicks a `JCheckBox`, an **ItemEvent** occurs. This event can be handled by an **ItemListener** object, which *must* implement method `itemStateChanged`. In this example, the event handling is performed by an instance of private *inner class* `CheckBoxHandler` (lines 40–59). Lines 34–36 create an instance of class `CheckBoxHandler` and register it with method `addItemListener` as the listener for both the `JCheckBox` objects.

`CheckBoxHandler` method `itemStateChanged` (lines 43–58) is called when the user clicks the `boldJCheckBox` or the `italicJCheckBox`. In this example, we don't need to

know which of the two `JCheckBox`s was clicked, just whether or not each one is checked. Line 48 uses `JCheckBox` method `isSelected` to determine if both `JCheckBox`s are selected. If so, line 49 creates a bold italic font by adding the `Font` constants `Font.BOLD` and `Font.ITALIC` for the font-style argument of the `Font` constructor. Line 50 determines whether the `boldJCheckBox` is selected, and if so line 51 creates a bold font. Line 52 determines whether the `italicJCheckBox` is selected, and if so line 53 creates an italic font. If none of the preceding conditions are true, line 55 creates a plain font using the `Font` constant `Font.PLAIN`. Finally, line 57 sets `textField`'s new font, which changes the font in the `JTextField` on the screen.

### *Relationship Between an Inner Class and Its Top-Level Class*

Class `CheckBoxHandler` used variables `boldJCheckBox` (Fig. 14.17, lines 48 and 50), `italicJCheckBox` (lines 48 and 52) and `textField` (line 57) even though they are *not* declared in the inner class. Recall that an inner class has a special relationship with its top-level class—it's allowed to access *all* the variables and methods of the top-level class. `CheckBoxHandler` method `itemStateChanged` (line 43–58) uses this relationship to determine which `JCheckBox`s are checked and to set the font on the `JTextField`. Notice that none of the code in inner class `CheckBoxHandler` requires an explicit reference to the top-level class object.

## 14.10.2 JRadioButton

**Radio buttons** (declared with class `JRadioButton`) are similar to checkboxes in that they have two states—selected and not selected (also called deselected). However, radio buttons normally appear as a **group** in which only one button can be selected at a time (see the output of Fig. 14.20). Selecting a different radio button forces all others to be deselected. Radio buttons are used to represent **mutually exclusive options** (i.e., multiple options in the group *cannot* be selected at the same time). The logical relationship between radio buttons is maintained by a **ButtonGroup** object (package `javax.swing`), which itself is not a GUI component. A `ButtonGroup` object organizes a group of buttons and is not itself displayed in a user interface. Rather, the individual `JRadioButton` objects from the group are displayed in the GUI.

### Common Programming Error 14.3

*Adding a `ButtonGroup` object (or an object of any other class that does not derive from `Component`) to a container results in a compilation error.*

The application of Figs. 14.19–14.20 is similar to that of Figs. 14.17–14.18. The user can alter the font style of a `JTextField`'s text. The application uses radio buttons that permit only a single font style in the group to be selected at a time. Class `RadioButtonTest` (Fig. 14.20) contains the `main` method that executes this application.

13    } // end main
14 } // end class RadioButtonTest

```

**Fig. 14.20** | Test class for RadioButtonFrame. (Part 1 of 2.)

**Fig. 14.20** | Test class for `RadioButtonFrame`. (Part 2 of 2.)

Lines 35–42 in the constructor (Fig. 14.19) create four `JRadioButton` objects and add them to the `JFrame`. Each `JRadioButton` is created with a constructor call like that in line 35. This constructor specifies the label that appears to the right of the `JRadioButton` by default and the initial state of the `JRadioButton`. A true second argument indicates that the `JRadioButton` should appear selected when it’s displayed.

Line 45 instantiates `ButtonGroup` object `radioGroup`. This object is the “glue” that forms the logical relationship between the four `JRadioButton` objects and allows only one of the four to be selected at a time. It’s possible that no `JRadioButtons` in a `ButtonGroup` are selected, but this can occur *only* if no preselected `JRadioButtons` are added to the `ButtonGroup` and the user has not selected a `JRadioButton` yet. Lines 46–49 use `ButtonGroup` method `add` to associate each of the `JRadioButtons` with `radioGroup`. If more than one selected `JRadioButton` object is added to the group, the selected one that was added first will be selected when the GUI is displayed.

`JRadioButtons`, like `JCheckBoxes`, generate `ItemEvents` when they’re clicked. Lines 59–66 create four instances of inner class `RadioButtonHandler` (declared at lines 70–84). In this example, each event-listener object is registered to handle the `ItemEvent` generated when the user clicks a particular `JRadioButton`. Notice that each `RadioButtonHandler` object is initialized with a particular `Font` object (created in lines 52–55).

Class `RadioButtonHandler` (line 70–84) implements interface `ItemListener` so it can handle `ItemEvents` generated by the `JRadioButtons`. The constructor stores the `Font` object it receives as an argument in the event-listener object’s instance variable `font` (declared at line 72). When the user clicks a `JRadioButton`, `radioGroup` turns off the previously selected `JRadioButton`, and method `itemStateChanged` (line 80–83) sets the font in the `JTextField` to the `Font` stored in the `JRadioButton`’s corresponding event-listener object. Notice that line 82 of inner class `RadioButtonHandler` uses the top-level class’s `textField` instance variable to set the font.

## 14.11 JComboBox; Using an Anonymous Inner Class for Event Handling

A combo box (sometimes called a **drop-down list**) enables the user to select one item from a list (Fig. 14.22). Combo boxes are implemented with class `JComboBox`, which extends class `JComponent`. `JComboBoxes` generate `ItemEvents` just as `JCheckBoxes` and `JRadioButtons` do. This example also demonstrates a special form of inner class that’s used frequently in event handling. The application (Figs. 14.21–14.22) uses a `JComboBox` to provide a list of four image-file names from which the user can select one image to display. When the user selects a name, the application displays the corresponding image as an `Icon` on a `JLabel`. Class `ComboBoxTest` (Fig. 14.22) contains the `main` method that executes this appli-

caution. The screen captures for this application show the JComboBox list after the selection was made to illustrate which image-file name was selected.

Lines 19–23 (Fig. 14.21) declare and initialize array icons with four new ImageIcon objects. String array names (lines 17–18) contains the names of the four image files that are stored in the same directory as the application.

```

1 // Fig. 14.21: ComboBoxFrame.java
2 // JComboBox that displays a list of image names.
3 import java.awt.FlowLayout;
4 import java.awt.event.ItemListener;
5 import java.awt.event.ItemEvent;
6 import javax.swing.JFrame;
7 import javax.swing.JLabel;
8 import javax.swing.JComboBox;
9 import javax.swing.Icon;
10 import javax.swing.ImageIcon;
11
12 public class ComboBoxFrame extends JFrame
13 {
14     private JComboBox imagesJComboBox; // combobox to hold names of icons
15     private JLabel label; // label to display selected icon
16
17     private static final String[] names =
18     { "bug1.gif", "bug2.gif", "travelbug.gif", "buganim.gif" };
19     private Icon[] icons = {
20         new ImageIcon( getClass().getResource( names[ 0 ] ) ),
21         new ImageIcon( getClass().getResource( names[ 1 ] ) ),
22         new ImageIcon( getClass().getResource( names[ 2 ] ) ),
23         new ImageIcon( getClass().getResource( names[ 3 ] ) ) };
24
25     // ComboBoxFrame constructor adds JComboBox to JFrame
26     public ComboBoxFrame()
27     {
28         super( "Testing JComboBox" );
29         setLayout( new FlowLayout() ); // set frame layout
30
31         imagesJComboBox = new JComboBox( names ); // set up JComboBox
32         imagesJComboBox.setMaximumRowCount( 3 ); // display three rows
33
34         imagesJComboBox.addItemListener(
35             new ItemListener() // anonymous inner class
36             {
37                 // handle JComboBox event
38                 public void itemStateChanged( ItemEvent event )
39                 {
40                     // determine whether item selected
41                     if ( event.getStateChange() == ItemEvent.SELECTED )
42                         label.setIcon( icons[
43                             imagesJComboBox.getSelectedIndex() ] );
44                 } // end method itemStateChanged
45             } // end anonymous inner class
46         ); // end call to addItemListener

```

**Fig. 14.21** | JComboBox that displays a list of image names. (Part 1 of 2.)

```

47
48     add( imagesJComboBox ); // add combobox to JFrame
49     label = new JLabel( icons[ 0 ] ); // display first icon
50     add( label ); // add label to JFrame
51 } // end ComboBoxFrame constructor
52 } // end class ComboBoxFrame

```

**Fig. 14.21** | JComboBox that displays a list of image names. (Part 2 of 2.)

```

1 // Fig. 14.22: ComboBoxTest.java
2 // Testing ComboBoxFrame.
3 import javax.swing.JFrame;
4
5 public class ComboBoxTest
6 {
7     public static void main( String[] args )
8     {
9         ComboBoxFrame comboBoxFrame = new ComboBoxFrame();
10        comboBoxFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        comboBoxFrame.setSize( 350, 150 ); // set frame size
12        comboBoxFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class ComboBoxTest

```

**Fig. 14.22** | Testing ComboBoxFrame.

At line 31, the constructor initializes a JComboBox object with the Strings in array names as the elements in the list. Each item in the list has an **index**. The first item is added at index 0, the next at index 1 and so forth. The first item added to a JComboBox appears as the currently selected item when the JComboBox is displayed. Other items are selected by clicking the JComboBox, then selecting an item from the list that appears.

Line 32 uses JComboBox method `setMaximumRowCount` to set the maximum number of elements that are displayed when the user clicks the JComboBox. If there are additional items, the JComboBox provides a **scrollbar** (see the first screen) that allows the user to scroll through all the elements in the list. The user can click the **scroll arrows** at the top and bottom of the scrollbar to move up and down through the list one element at a time, or else drag the **scroll box** in the middle of the scrollbar up and down. To drag the scroll box, position the mouse cursor on it, hold the mouse button down and move the mouse. In this example, the drop-down list is too short to drag the scroll box, so you can click the up and down arrows or use your mouse's wheel to scroll through the four items in the list.

### Look-and-Feel Observation 14.12

*Set the maximum row count for a JComboBox to a number of rows that prevents the list from expanding outside the bounds of the window in which it's used.*

Line 48 attaches the JComboBox to the ComboBoxFrame's FlowLayout (set in line 29). Line 49 creates the JLabel that displays ImageIcon and initializes it with the first ImageIcon in array `icons`. Line 50 attaches the JLabel to the ComboBoxFrame's FlowLayout.

### Using an Anonymous Inner Class for Event Handling

Lines 34–46 are one statement that declares the event listener's class, creates an object of that class and registers it as the listener for `imagesJComboBox`'s `ItemEvents`. This event-listener object is an instance of an **anonymous inner class**—an inner class that's declared without a name and typically appears inside a method declaration. *As with other inner classes, an anonymous inner class can access its top-level class's members.* However, an anonymous inner class has limited access to the local variables of the method in which it's declared. Since an anonymous inner class has no name, one object of the class must be created at the point where the class is declared (starting at line 35).

### Software Engineering Observation 14.3

*An anonymous inner class declared in a method can access the instance variables and methods of the top-level class object that declared it, as well as the method's final local variables, but cannot access the method's non-final local variables.*

Lines 34–46 are a call to `imagesJComboBox`'s `addItemListener` method. The argument to this method must be an object that *is an ItemListener* (i.e., any object of a class that implements `ItemListener`). Lines 35–45 are a class-instance creation expression that declares an anonymous inner class and creates one object of that class. A reference to that object is then passed as the argument to `addItemListener`. The syntax `ItemListener()` after `new` begins the declaration of an anonymous inner class that implements interface `ItemListener`. This is similar to beginning a class declaration with

```
public class MyHandler implements ItemListener
```

The opening left brace at 36 and the closing right brace at line 45 delimit the body of the anonymous inner class. Lines 38–44 declare the `ItemListener`'s `itemStateChanged` method. When the user makes a selection from `imagesJComboBox`, this method sets `label`'s `Icon`. The `Icon` is selected from array `icons` by determining the index of the selected item in the JComboBox with method `getSelectedIndex` in line 43. For each item selected from a JComboBox, another item is first deselected—so two `ItemEvents` occur

when an item is selected. We wish to display only the icon for the item the user just selected. For this reason, line 41 determines whether `ItemEvent` method `getStateChange` returns `ItemEvent.SELECTED`. If so, lines 42–43 set `label`'s icon.

#### Software Engineering Observation 14.4

*Like any other class, when an anonymous inner class implements an interface, the class must implement every method in the interface.*

The syntax shown in lines 35–45 for creating an event handler with an anonymous inner class is similar to the code that would be generated by a Java integrated development environment (IDE). Typically, an IDE enables you to design a GUI visually, then it generates code that implements the GUI. You simply insert statements in the event-handling methods that declare how to handle each event.

## 14.12 JList

A list displays a series of items from which the user may *select one or more items* (see the output of Fig. 14.24). Lists are created with class `JList`, which directly extends class `JComponent`. Class `JList` supports **single-selection lists** (which allow only one item to be selected at a time) and **multiple-selection lists** (which allow any number of items to be selected). In this section, we discuss single-selection lists.

The application of Figs. 14.23–14.24 creates a `JList` containing 13 color names. When a color name is clicked in the `JList`, a `ListSelectionEvent` occurs and the application changes the background color of the application window to the selected color. Class `ListTest` (Fig. 14.24) contains the `main` method that executes this application.

1 // Fig. 14.24: ListTest.java
2 // Selecting colors from a JList.
3 import javax.swing.JFrame;
4
5 public class ListTest
6 {
7     public static void main( String[] args )
8     {
9         ListFrame listFrame = new ListFrame(); // create ListFrame
10        listFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        listFrame.setSize( 350, 150 ); // set frame size
12        listFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class ListTest

```

**Fig. 14.24** | Test class for ListFrame.

Line 29 (Fig. 14.23) creates `JList` object `colorJList`. The argument to the `JList` constructor is the array of `Objects` (in this case `Strings`) to display in the list. Line 30 uses `JList` method `setVisibleRowCount` to determine the number of items visible in the list.

Line 33 uses `JList` method `setSelectionMode` to specify the list's **selection mode**. Class `ListSelectionMode1` (of package `javax.swing`) declares three constants that specify a `JList`'s selection mode—`SINGLE_SELECTION` (which allows only one item to be selected at a time), `SINGLE_INTERVAL_SELECTION` (for a multiple-selection list that allows selection of several contiguous items) and `MULTIPLE_INTERVAL_SELECTION` (for a multiple-selection list that does not restrict the items that can be selected).

Unlike a `JComboBox`, a `JList` *does not provide a scrollbar* if there are more items in the list than the number of visible rows. In this case, a `JScrollPane` object is used to provide the scrolling capability. Line 36 adds a new instance of class `JScrollPane` to the `JFrame`. The `JScrollPane` constructor receives as its argument the `JComponent` that needs scrolling functionality (in this case, `colorJList`). Notice in the screen captures that a scrollbar created by the `JScrollPane` appears at the right side of the `JList`. By default, the scrollbar appears only when the number of items in the `JList` exceeds the number of visible items.

Lines 38–48 use `JList` method `addListSelectionListener` to register an object that implements `ListSelectionListener` (package `javax.swing.event`) as the listener for the `JList`'s selection events. Once again, we use an instance of an anonymous inner class (lines 39–47) as the listener. In this example, when the user makes a selection from `colorJList`, method `valueChanged` (line 42–46) should change the background color of the `ListFrame` to the selected color. This is accomplished in lines 44–45. Note the use of `JFrame` method `getContentPane` in line 44. Each `JFrame` actually consists of *three layers*—the *background*, the *content pane* and the *glass pane*. The content pane appears in front of the background and is where the GUI components in the `JFrame` are displayed. The glass pane is used to display tool tips and other items that should appear in front of the GUI components on the screen. The content pane completely hides the background of the `JFrame`; thus, to change the background color behind the GUI components, you must change the content pane's background color. Method `getContentPane` returns a reference to the `JFrame`'s content pane (an object of class `Container`). In line 44, we then use that reference to call method `setBackground`, which sets the content pane's background color to an element in the `colors` array. The color is selected from the array by using the selected item's index. `JList` method `getSelectedIndex` returns the selected item's index. As with arrays and `JComboBoxes`, `JList` indexing is zero based.

## 14.13 Multiple-Selection Lists

A **multiple-selection list** enables the user to select many items from a `JList` (see the output of Fig. 14.26). A `SINGLE_INTERVAL_SELECTION` list allows selecting a contiguous range of items. To do so, click the first item, then press and hold the *Shift* key while clicking the last item in the range. A `MULTIPLE_INTERVAL_SELECTION` list (the default) allows continuous range selection as described for a `SINGLE_INTERVAL_SELECTION` list. Such a list also allows miscellaneous items to be selected by pressing and holding the *Ctrl* key while clicking each item to select. To deselect an item, press and hold the *Ctrl* key while clicking the item a second time.

The application of Figs. 14.25–14.26 uses multiple-selection lists to copy items from one `JList` to another. One list is a `MULTIPLE_INTERVAL_SELECTION` list and the other is a

SINGLE\_INTERVAL\_SELECTION list. When you execute the application, try using the selection techniques described previously to select items in both lists.

```

9 import javax.swing.JScrollPane;
10 import javax.swing.ListSelectionModel;
11
12 public class MultipleSelectionFrame extends JFrame
13 {
14     private JList colorJList; // list to hold color names
15     private JList copyJList; // list to copy color names into
16     private JButton copyJButton; // button to copy selected names
17     private static final String[] colorNames = { "Black", "Blue", "Cyan",
18         "Dark Gray", "Gray", "Green", "Light Gray", "Magenta", "Orange",
19         "Pink", "Red", "White", "Yellow" };
20
21     // MultipleSelectionFrame constructor
22     public MultipleSelectionFrame()
23     {
24         super( "Multiple Selection Lists" );
25         setLayout( new FlowLayout() ); // set frame layout
26
27         colorJList = new JList( colorNames ); // holds names of all colors
28         colorJList.setVisibleRowCount( 5 ); // show five rows
29         colorJList.setSelectionMode(
30             ListSelectionModel.MULTIPLE_INTERVAL_SELECTION );
31         add( new JScrollPane( colorJList ) ); // add list with scrollpane
32
33         copyJButton = new JButton( "Copy >>>" ); // create copy button
34         copyJButton.addActionListener(
35             new ActionListener() // anonymous inner class
36             {
37                 // handle button event
38                 public void actionPerformed( ActionEvent event )
39                 {
40                     // place selected values in copyJList
41                     copyJList.setListData( colorJList.getSelectedValues() );
42                 } // end method actionPerformed
43             } // end anonymous inner class
44         ); // end call to addActionListener
45
46         add( copyJButton ); // add copy button to JFrame
47
48         copyJList = new JList(); // create list to hold copied color names
49

```

**Fig. 14.25** | JList that allows multiple selections. (Part 1 of 2.)

```

50     copyJList.setVisibleRowCount( 5 ); // show 5 rows
51     copyJList.setFixedCellWidth( 100 ); // set width
52     copyJList.setFixedCellHeight( 15 ); // set height
53     copyJList.setSelectionMode(
54         ListSelectionMode.SINGLE_INTERVAL_SELECTION );
55     add( new JScrollPane( copyJList ) ); // add list with scrollpane
56 } // end MultipleSelectionFrame constructor
57 } // end class MultipleSelectionFrame

```

**Fig. 14.25** | JList that allows multiple selections. (Part 2 of 2.)

```

1 // Fig. 14.26: MultipleSelectionTest.java
2 // Testing MultipleSelectionFrame.
3 import javax.swing.JFrame;
4
5 public class MultipleSelectionTest
6 {
7     public static void main( String[] args )
8     {
9         MultipleSelectionFrame multipleSelectionFrame =
10             new MultipleSelectionFrame();
11         multipleSelectionFrame.setDefaultCloseOperation(
12             JFrame.EXIT_ON_CLOSE );
13         multipleSelectionFrame.setSize( 350, 150 ); // set frame size
14         multipleSelectionFrame.setVisible( true ); // display frame
15     } // end main
16 } // end class MultipleSelectionTest

```

**Fig. 14.26** | Test class for MultipleSelectionFrame.

Line 27 of Fig. 14.25 creates JList colorJList and initializes it with the Strings in the array colorNames. Line 28 sets the number of visible rows in colorJList to 5. Lines 29–30 specify that colorJList is a MULTIPLE\_INTERVAL\_SELECTION list. Line 31 adds a new JScrollPane containing colorJList to the JFrame. Lines 49–55 perform similar tasks for copyJList, which is declared as a SINGLE\_INTERVAL\_SELECTION list. If a JList does not contain items, it will not display in a FlowLayout. For this reason, lines 51–52 use JList methods **setFixedCellWidth** and **setFixedCellHeight** to set copyJList's width to 100 pixels and the height of each item in the JList to 15 pixels, respectively.

Normally, an event generated by another GUI component (known as an **external event**) specifies when the multiple selections in a JList should be processed. In this example, the user clicks the JButton called copyJButton to trigger the event that copies the selected items in colorJList to copyJList.

Lines 34–45 declare, create and register an `ActionListener` for the `copyJButton`. When the user clicks `copyJButton`, method `actionPerformed` (lines 39–43) uses `JList` method `setListData` to set the items displayed in `copyJList`. Line 42 calls `colorJList`'s method `getSelectedValues`, which returns an array of `Objects` representing the selected items in `colorJList`. In this example, the returned array is passed as the argument to `copyJList`'s `setListData` method.

You might be wondering why `copyJList` can be used in line 42 even though the application does not create the object to which it refers until line 49. Remember that method `actionPerformed` (lines 39–43) does not execute until the user presses the `copyJButton`, which cannot occur until after the constructor completes execution and the application displays the GUI. At that point in the application's execution, `copyJList` is already initialized with a new `JList` object.

## 14.14 Mouse Event Handling

This section presents the `MouseListener` and `MouseMotionListener` event-listener interfaces for handling **mouse events**. Mouse events can be processed for any GUI component that derives from `java.awt.Component`. The methods of interfaces `MouseListener` and `MouseMotionListener` are summarized in Figure 14.27. Package `javax.swing.event` contains interface `MouseEvent`, which extends interfaces `MouseListener` and `MouseMotionListener` to create a single interface containing all the `MouseListener` and `MouseMotionListener` methods. The `MouseListener` and `MouseMotionListener` methods are called when the mouse interacts with a `Component` if appropriate event-listener objects are registered for that `Component`.

Each of the mouse event-handling methods receives as an argument a `MouseEvent` object that contains information about the mouse event that occurred, including the *x*- and *y*-coordinates of its location. These coordinates are measured from the upper-left corner of the GUI component on which the event occurred. The *x*-coordinates start at 0 and increase from left to right. The *y*-coordinates start at 0 and increase from top to bottom. The methods and constants of class `MouseEvent` (`MouseEvent`'s superclass) enable you to determine which mouse button the user clicked.

### MouseListener and MouseMotionListener interface methods

#### *Methods of interface MouseListener*

```
public void mousePressed( MouseEvent event )
```

Called when a mouse button is *pressed* while the mouse cursor is on a component.

```
public void mouseClicked( MouseEvent event )
```

Called when a mouse button is *pressed and released* while the mouse cursor remains stationary on a component. This event is always preceded by a call to `mousePressed`.

```
public void mouseReleased( MouseEvent event )
```

Called when a mouse button is *released after being pressed*. This event is always preceded by a call to `mousePressed` and one or more calls to `mouseDragged`.

**Fig. 14.27** | `MouseListener` and `MouseMotionListener` interface methods. (Part 1 of 2.)

## MouseListener and MouseMotionListener interface methods

```
public void mouseEntered( MouseEvent event )
```

Called when the mouse cursor *enters* the bounds of a component.

```
public void mouseExited( MouseEvent event )
```

Called when the mouse cursor *leaves* the bounds of a component.

*Methods of interface MouseMotionListener*

```
public void mouseDragged( MouseEvent event )
```

Called when the mouse button is *pressed* while the mouse cursor is on a component and the mouse is *moved* while the mouse button *remains pressed*. This event is always preceded by a call to `mousePressed`. All drag events are sent to the component on which the user began to drag the mouse.

```
public void mouseMoved( MouseEvent event )
```

Called when the mouse is *moved* (with no mouse buttons pressed) when the mouse cursor is on a component. All move events are sent to the component over which the mouse is currently positioned.

**Fig. 14.27** | MouseListener and MouseMotionListener interface methods. (Part 2 of 2.)

### Software Engineering Observation 14.5

*Calls to `mouseDragged` are sent to the `MouseMotionListener` for the Component on which the drag started. Similarly, the `mouseReleased` call at the end of a drag operation is sent to the `MouseListener` for the Component on which the drag operation started.*

Java also provides interface **MouseWheelListener** to enable applications to respond to the *rotation of a mouse wheel*. This interface declares method **mouseWheelMoved**, which receives a **MouseWheelEvent** as its argument. Class `MouseWheelEvent` (a subclass of `MouseEvent`) contains methods that enable the event handler to obtain information about the amount of wheel rotation.

### Tracking Mouse Events on a JPanel

The `MouseTracker` application (Figs. 14.28–14.29) demonstrates the `MouseListener` and `MouseMotionListener` interface methods. The event-handler class (lines 36–90) implements both interfaces. You *must* declare all seven methods from these two interfaces when your class implements them both. Each mouse event in this example displays a `String` in the `JLabel` called `statusBar` that is attached to the bottom of the window.

```
1 // Fig. 14.28: MouseTrackerFrame.java
2 // Demonstrating mouse events.
3 import java.awt.Color;
4 import java.awt.BorderLayout;
5 import java.awt.event.MouseListener;
6 import java.awt.event.MouseMotionListener;
7 import java.awt.event.MouseEvent;
```

**Fig. 14.28** | Mouse event handling. (Part 1 of 3.)

```
8 import javax.swing.JFrame;
9 import javax.swing.JLabel;
10 import javax.swing.JPanel;
11
12 public class MouseTrackerFrame extends JFrame
13 {
14     private JPanel mousePanel; // panel in which mouse events will occur
15     private JLabel statusBar; // label that displays event information
16
17     // MouseTrackerFrame constructor sets up GUI and
18     // registers mouse event handlers
19     public MouseTrackerFrame()
20     {
21         super( "Demonstrating Mouse Events" );
22
23         mousePanel = new JPanel(); // create panel
24         mousePanel.setBackground( Color.WHITE ); // set background color
25         add( mousePanel, BorderLayout.CENTER ); // add panel to JFrame
26
27         statusBar = new JLabel( "Mouse outside JPanel" );
28         add( statusBar, BorderLayout.SOUTH ); // add label to JFrame
29
30         // create and register listener for mouse and mouse motion events
31         MouseHandler handler = new MouseHandler();
32         mousePanel.addMouseListener( handler );
33         mousePanel.addMouseMotionListener( handler );
34     } // end MouseTrackerFrame constructor
35
36     private class MouseHandler implements MouseListener,
37         MouseMotionListener
38     {
39         // MouseListener event handlers
40         // handle event when mouse released immediately after press
41         public void mouseClicked( MouseEvent event )
42         {
43             statusBar.setText( String.format( "Clicked at [%d, %d]",
44                 event.getX(), event.getY() ) );
45         } // end method mouseClicked
46
47         // handle event when mouse pressed
48         public void mousePressed( MouseEvent event )
49         {
50             statusBar.setText( String.format( "Pressed at [%d, %d]",
51                 event.getX(), event.getY() ) );
52         } // end method mousePressed
53
54         // handle event when mouse released
55         public void mouseReleased( MouseEvent event )
56         {
57             statusBar.setText( String.format( "Released at [%d, %d]",
58                 event.getX(), event.getY() ) );
59         } // end method mouseReleased
60     }
```

**Fig. 14.28** | Mouse event handling. (Part 2 of 3.)

```

61     // handle event when mouse enters area
62     public void mouseEntered( MouseEvent event )
63     {
64         statusBar.setText( String.format( "Mouse entered at [%d, %d]",
65             event.getX(), event.getY() ) );
66         mousePanel.setBackground( Color.GREEN );
67     } // end method mouseEntered
68
69     // handle event when mouse exits area
70     public void mouseExited( MouseEvent event )
71     {
72         statusBar.setText( "Mouse outside JPanel" );
73         mousePanel.setBackground( Color.WHITE );
74     } // end method mouseExited
75
76     // MouseMotionListener event handlers
77     // handle event when user drags mouse with button pressed
78     public void mouseDragged( MouseEvent event )
79     {
80         statusBar.setText( String.format( "Dragged at [%d, %d]",
81             event.getX(), event.getY() ) );
82     } // end method mouseDragged
83
84     // handle event when user moves mouse
85     public void mouseMoved( MouseEvent event )
86     {
87         statusBar.setText( String.format( "Moved at [%d, %d]",
88             event.getX(), event.getY() ) );
89     } // end method mouseMoved
90 } // end inner class MouseHandler
91 } // end class MouseTrackerFrame

```

**Fig. 14.28** | Mouse event handling. (Part 3 of 3.)

Line 23 in Fig. 14.28 creates `JPanel` `mousePanel`. This `JPanel`'s mouse events will be tracked by the application. Line 24 sets `mousePanel`'s background color to white. When the user moves the mouse into the `mousePanel`, the application will change `mousePanel`'s background color to green. When the user moves the mouse out of the `mousePanel`, the application will change the background color back to white. Line 25 attaches `mousePanel` to the `JFrame`. As you learned in Section 14.5, you typically must specify the layout of the GUI components in a `JFrame`. In that section, we introduced the layout manager `FlowLayout`. Here we use the default layout of a `JFrame`'s content pane—**BorderLayout**. This layout manager arranges components into five regions: **NORTH**, **SOUTH**, **EAST**, **WEST** and **CENTER**. **NORTH** corresponds to the top of the container. This example uses the **CENTER** and **SOUTH** regions. Line 25 uses a two-argument version of method `add` to place `mousePanel` in the **CENTER** region. The `BorderLayout` automatically sizes the component in the **CENTER** to use all the space in the `JFrame` that is not occupied by components in the other regions. Section 14.18.2 discusses `BorderLayout` in more detail.

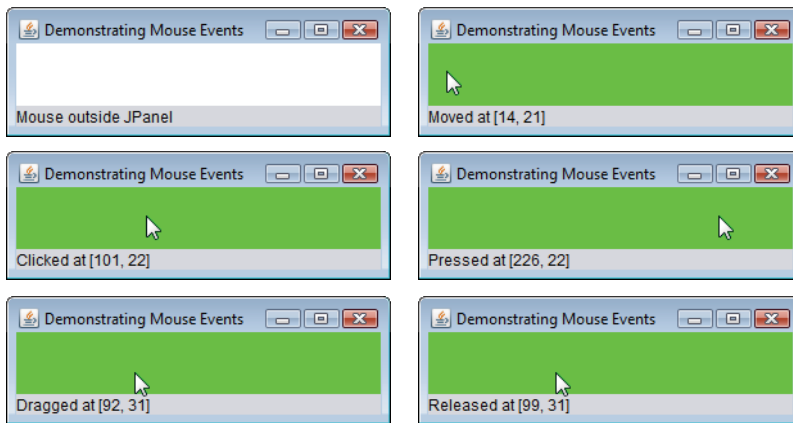

Lines 27–28 in the constructor declare `JLabel` `statusBar` and attach it to the `JFrame`'s **SOUTH** region. This `JLabel` occupies the width of the `JFrame`. The region's height is determined by the `JLabel`.

```

1 // Fig. 14.29: MouseTrackerFrame.java
2 // Testing MouseTrackerFrame.
3 import javax.swing.JFrame;
4
5 public class MouseTracker
6 {
7     public static void main( String[] args )
8     {
9         MouseTrackerFrame mouseTrackerFrame = new MouseTrackerFrame();
10        mouseTrackerFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        mouseTrackerFrame.setSize( 300, 100 ); // set frame size
12        mouseTrackerFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class MouseTracker

```

**Fig. 14.29** | Test class for MouseTrackerFrame.

Line 31 creates an instance of inner class `MouseHandler` (lines 36–90) called `handler` that responds to mouse events. Lines 32–33 register `handler` as the listener for `mousePanel`'s mouse events. Methods `addMouseListener` and `addMouseMotionListener` are inherited indirectly from class `Component` and can be used to register `MouseListener`s and `MouseMotionListener`s, respectively. A `MouseHandler` object *is a* `MouseListener` and *is a* `MouseMotionListener` because the class implements *both* interfaces. We chose to implement both interfaces here to demonstrate a class that implements more than one interface, but we could have implemented interface `MouseListener` instead.]

When the mouse enters and exits `mousePanel`'s area, methods `mouseEntered` (lines 62–67) and `mouseExited` (lines 70–74) are called, respectively. Method `mouseEntered` displays a message in the status bar indicating that the mouse entered the `JPanel` and changes the background color to green. Method `mouseExited` displays a message in the status bar indicating that the mouse is outside the `JPanel` (see the first sample output window) and changes the background color to white.

The other five events display a string in the status bar that includes the event and the coordinates at which it occurred. `MouseEvent` methods `getX` and `getY` return the *x*- and *y*-coordinates, respectively, of the mouse at the time the event occurred.

## 14.15 Adapter Classes

Many event-listener interfaces, such as `MouseListener` and `MouseMotionListener`, contain multiple methods. It's not always desirable to declare every method in an event-listener interface. For instance, an application may need only the `mouseClicked` handler from `MouseListener` or the `mouseDragged` handler from `MouseMotionListener`. Interface `WindowListener` specifies seven window event-handling methods. For many of the listener interfaces that have multiple methods, packages `java.awt.event` and `javax.swing.event` provide event-listener adapter classes. An **adapter class** implements an interface and provides a default implementation (with an empty method body) of each method in the interface. Figure 14.30 shows several `java.awt.event` adapter classes and the interfaces they implement. You can extend an adapter class to inherit the default implementation of every method and subsequently override only the method(s) you need for event handling.

### Software Engineering Observation 14.6

*When a class implements an interface, the class has an is-a relationship with that interface. All direct and indirect subclasses of that class inherit this interface. Thus, an object of a class that extends an event-adapter class is an object of the corresponding event-listener type (e.g., an object of a subclass of `MouseAdapter` is a `MouseListener`).*

| Event-adapter class in <code>java.awt.event</code> | Implements interface             |
|----------------------------------------------------|----------------------------------|
| <code>ComponentAdapter</code>                      | <code>ComponentListener</code>   |
| <code>ContainerAdapter</code>                      | <code>ContainerListener</code>   |
| <code>FocusAdapter</code>                          | <code>FocusListener</code>       |
| <code>KeyAdapter</code>                            | <code>KeyListener</code>         |
| <code>MouseAdapter</code>                          | <code>MouseListener</code>       |
| <code>MouseMotionAdapter</code>                    | <code>MouseMotionListener</code> |
| <code>WindowAdapter</code>                         | <code>WindowListener</code>      |

**Fig. 14.30** | Event-adapter classes and the interfaces they implement in package `java.awt.event`.

### Extending `MouseAdapter`

The application of Figs. 14.31–14.32 demonstrates how to determine the number of mouse clicks (i.e., the click count) and how to distinguish between the different mouse buttons. The event listener in this application is an object of inner class `MouseClickedHandler` (lines 25–45) that extends `MouseAdapter`, so we can declare just the `mouseClicked` method we need in this example.

```

1 // Fig. 14.31: MouseDetailsFrame.java
2 // Demonstrating mouse clicks and distinguishing between mouse buttons.
3 import java.awt.BorderLayout;
4 import java.awt.event.MouseAdapter;

```

**Fig. 14.31** | Left, center and right mouse-button clicks. (Part I of 2.)

```

5 import java.awt.event.MouseEvent;
6 import javax.swing.JFrame;
7 import javax.swing.JLabel;
8
9 public class MouseDetailsFrame extends JFrame
10 {
11     private String details; // String that is displayed in the statusBar
12     private JLabel statusBar; // JLabel that appears at bottom of window
13
14     // constructor sets title bar String and register mouse listener
15     public MouseDetailsFrame()
16     {
17         super( "Mouse clicks and buttons" );
18
19         statusBar = new JLabel( "Click the mouse" );
20         add( statusBar, BorderLayout.SOUTH );
21         addMouseListener( new MouseClickHandler() ); // add handler
22     } // end MouseDetailsFrame constructor
23
24     // inner class to handle mouse events
25     private class MouseClickHandler extends MouseAdapter
26     {
27         // handle mouse-click event and determine which button was pressed
28         public void mouseClicked( MouseEvent event )
29         {
30             int xPos = event.getX(); // get x-position of mouse
31             int yPos = event.getY(); // get y-position of mouse
32
33             details = String.format( "Clicked %d time(s)",
34                                     event.getClickCount() );
35
36             if ( event.isMetaDown() ) // right mouse button
37                 details += " with right mouse button";
38             else if ( event.isAltDown() ) // middle mouse button
39                 details += " with center mouse button";
40             else // left mouse button
41                 details += " with left mouse button";
42
43             statusBar.setText( details ); // display message in statusBar
44         } // end method mouseClicked
45     } // end private inner class MouseClickHandler
46 } // end class MouseDetailsFrame

```

**Fig. 14.31** | Left, center and right mouse-button clicks. (Part 2 of 2.)

```

1 // Fig. 14.32: MouseDetails.java
2 // Testing MouseDetailsFrame.
3 import javax.swing.JFrame;
4
5 public class MouseDetails
6 {

```

**Fig. 14.32** | Test class for MouseDetailsFrame. (Part 1 of 2.)

```

7   public static void main( String[] args )
8   {
9       MouseDetailsFrame mouseDetailsFrame = new MouseDetailsFrame();
10      mouseDetailsFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11      mouseDetailsFrame.setSize( 400, 150 ); // set frame size
12      mouseDetailsFrame.setVisible( true ); // display frame
13  } // end main
14 } // end class MouseDetails

```

**Fig. 14.32** | Test class for `MouseDetailsFrame`. (Part 2 of 2.)

#### Common Programming Error 14.4

*If you extend an adapter class and misspell the name of the method you're overriding, your method simply becomes another method in the class. This is a logic error that is difficult to detect, since the program will call the empty version of the method inherited from the adapter class.*

A user of a Java application may be on a system with a one-, two- or three-button mouse. Java provides a mechanism to distinguish among mouse buttons. Class `MouseEvent` inherits several methods from class `InputEvent` that can distinguish among mouse buttons on a multibutton mouse or can mimic a multibutton mouse with a combined keystroke and mouse-button click. Figure 14.33 shows the `InputEvent` methods used to distinguish among mouse-button clicks. Java assumes that every mouse contains a left mouse button. Thus, it's simple to test for a left-mouse-button click. However, users with a one- or two-button mouse must use a combination of keystrokes and mouse-button clicks at the same time to simulate the missing buttons on the mouse. In the case of a one- or two-button mouse, a Java application assumes that the center mouse button is clicked if the user holds down the *Alt* key and clicks the left mouse button on a two-button mouse or the only mouse button on a one-button mouse. In the case of a one-button mouse, a Java application assumes that the right mouse button is clicked if the user holds down the *Meta* key (sometimes called the *Command* key or the "Apple" key on a Mac) and clicks the mouse button.

| InputEvent method         | Description                                                                                                                                                                                                                                                         |
|---------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>isMetaDown()</code> | Returns true when the user clicks the <i>right mouse button</i> on a mouse with two or three buttons. To simulate a right-mouse-button click on a one-button mouse, the user can hold down the <i>Meta</i> key on the keyboard and click the mouse button.          |
| <code>isAltDown()</code>  | Returns true when the user clicks the <i>middle mouse button</i> on a mouse with three buttons. To simulate a middle-mouse-button click on a one- or two-button mouse, the user can press the <i>Alt</i> key and click the only or left mouse button, respectively. |

**Fig. 14.33** | InputEvent methods that help determine whether the right or center mouse button was clicked.

Line 21 of Fig. 14.31 registers a `MouseListener` for the `MouseDetailsFrame`. The event listener is an object of class `MouseClickedHandler`, which extends `MouseAdapter`. This enables us to declare only method `MouseClicked` (lines 28–44). This method first captures the coordinates where the event occurred and stores them in local variables `xPos` and `yPos` (lines 30–31). Lines 33–34 create a `String` called `details` containing the number of consecutive mouse clicks, which is returned by `MouseEvent` method `getClickCount` at line 34. Lines 36–41 use methods `isMetaDown` and `isAltDown` to determine which mouse button the user clicked and append an appropriate `String` to `details` in each case. The resulting `String` is displayed in the `statusBar`. Class `MouseDetails` (Fig. 14.32) contains the main method that executes the application. Try clicking with each of your mouse’s buttons repeatedly to see the click count increment.

## 14.16 JPanel Subclass for Drawing with the Mouse

Section 14.14 showed how to track mouse events in a `JPanel`. In this section, we use a `JPanel` as a **dedicated drawing area** in which the user can draw by dragging the mouse. In addition, this section demonstrates an event listener that extends an adapter class.

### *Method paintComponent*

Lightweight Swing components that extend class `JComponent` (such as `JPanel`) contain method `paintComponent`, which is called when a lightweight Swing component is displayed. By overriding this method, you can specify how to draw shapes using Java’s graphics capabilities. When customizing a `JPanel` for use as a dedicated drawing area, the subclass should override method `paintComponent` and call the superclass version of `paintComponent` as the first statement in the body of the overridden method to ensure that the component displays correctly. The reason is that subclasses of `JComponent` support **transparency**. To display a component correctly, the program must determine whether the component is transparent. The code that determines this is in superclass `JComponent`’s `paintComponent` implementation. When a component is transparent, `paintComponent` will not clear its background when the program displays the component. When a component is **opaque**, `paintComponent` clears the component’s background before the component is displayed. The transparency of a Swing lightweight component can be set with method `setOpaque` (a `false` argument indicates that the component is transparent).

### Error-Prevention Tip 14.1

In a `JComponent` subclass's `paintComponent` method, the first statement should always call the superclass's `paintComponent` method to ensure that an object of the subclass displays correctly.

### Common Programming Error 14.5

If an overridden `paintComponent` method does not call the superclass's version, the subclass component may not display properly. If an overridden `paintComponent` method calls the superclass's version after other drawing is performed, the drawing will be erased.

## Defining the Custom Drawing Area

The Painter application of Figs. 14.34–14.35 demonstrates a customized subclass of `JPanel` that is used to create a dedicated drawing area. The application uses the mouse-Draged event handler to create a simple drawing application. The user can draw pictures by dragging the mouse on the `JPanel`. This example does not use method `mouseMoved`, so our *event-listener class* (the *anonymous inner class* at lines 22–34) extends `MouseMotionAdapter`. Since this class already declares both `mouseMoved` and `mouseDragged`, we can simply override `mouseDragged` to provide the event handling this application requires.

```

1 // Fig. 14.34: PaintPanel.java
2 // Using class MouseMotionAdapter.
3 import java.awt.Point;
4 import java.awt.Graphics;
5 import java.awt.event.MouseEvent;
6 import java.awt.event.MouseMotionAdapter;
7 import javax.swing.JPanel;
8
9 public class PaintPanel extends JPanel
10 {
11     private int pointCount = 0; // count number of points
12
13     // array of 10000 java.awt.Point references
14     private Point[] points = new Point[ 10000 ];
15
16     // set up GUI and register mouse event handler
17     public PaintPanel()
18     {
19         // handle frame mouse motion event
20         addMouseMotionListener(
21
22             new MouseMotionAdapter() // anonymous inner class
23             {
24                 // store drag coordinates and repaint
25                 public void mouseDragged( MouseEvent event )
26                 {
27                     if ( pointCount < points.length )
28                     {

```

**Fig. 14.34** | Adapter class used to implement event handlers. (Part I of 2.)

```

29         points[ pointCount ] = event.getPoint(); // find point
30         ++pointCount; // increment number of points in array
31         repaint(); // repaint JFrame
32     } // end if
33 } // end method mouseDragged
34 } // end anonymous inner class
35 ); // end call to addMouseListener
36 } // end PaintPanel constructor
37
38 // draw ovals in a 4-by-4 bounding box at specified locations on window
39 public void paintComponent( Graphics g )
40 {
41     super.paintComponent( g ); // clears drawing area
42
43     // draw all points in array
44     for ( int i = 0; i < pointCount; i++ )
45         g.fillOval( points[ i ].x, points[ i ].y, 4, 4 );
46 } // end method paintComponent
47 } // end class PaintPanel

```

**Fig. 14.34** | Adapter class used to implement event handlers. (Part 2 of 2.)

Class `PaintPanel` (Fig. 14.34) extends `JPanel` to create the dedicated drawing area. Lines 3–7 import the classes used in class `PaintPanel`. Class **Point** (package `java.awt`) represents an  $x$ - $y$  coordinate. We use objects of this class to store the coordinates of each mouse drag event. Class **Graphics** is used to draw.

In this example, we use an array of 10,000 `Points` (line 14) to store the location at which each mouse drag event occurs. As you’ll see, method `paintComponent` uses these `Points` to draw. Instance variable `pointCount` (line 11) maintains the total number of `Points` captured from mouse drag events so far.

Lines 20–35 register a `MouseListener` to listen for the `PaintPanel`’s mouse motion events. Lines 22–34 create an object of an anonymous inner class that extends the adapter class `MouseMotionAdapter`. Recall that `MouseMotionAdapter` implements `MouseListener`, so the *anonymous inner class* object is a `MouseListener`. The anonymous inner class inherits default `mouseMoved` and `mouseDragged` implementations, so it already implements all the interface’s methods. However, the default methods do nothing when they’re called. So, we override method `mouseDragged` at lines 25–33 to capture the coordinates of a mouse drag event and store them as a `Point` object. Line 27 ensures that we store the event’s coordinates *only* if there are still empty elements in the array. If so, line 29 invokes the `MouseEvent`’s `getPoint` method to obtain the `Point` where the event occurred and stores it in the array at index `pointCount`. Line 30 increments the `pointCount`, and line 31 calls method `repaint` (inherited indirectly from class `Component`) to indicate that the `PaintPanel` should be refreshed on the screen as soon as possible with a call to the `PaintPanel`’s `paintComponent` method.

Method `paintComponent` (lines 39–46), which receives a `Graphics` parameter, is called automatically any time the `PaintPanel` needs to be displayed on the screen—such as when the GUI is first displayed—or refreshed on the screen—such as when method `repaint` is called or when the GUI component has been hidden by another window on the screen and subsequently becomes visible again.

### Look-and-Feel Observation 14.13

Calling `repaint` for a Swing GUI component indicates that the component should be re-freshed on the screen as soon as possible. The component's background is cleared only if the component is opaque. `JComponent` method `setOpaque` can be passed a `boolean` argument indicating whether the component is opaque (`true`) or transparent (`false`).

Line 41 invokes the superclass version of `paintComponent` to clear the `PaintPanel`'s background (`JPanel`s are opaque by default). Lines 44–45 draw an oval at the location specified by each `Point` in the array (up to the `pointCount`). Graphics method `fillOval` draws a solid oval. The method's four parameters represent a rectangular area (called the bounding box) in which the oval is displayed. The first two parameters are the upper-left *x*-coordinate and the upper-left *y*-coordinate of the rectangular area. The last two coordinates represent the rectangular area's width and height. Method `fillOval` draws the oval so it touches the middle of each side of the rectangular area. In line 45, the first two arguments are specified by using class `Point`'s two public instance variables—`x` and `y`. The loop terminates when `pointCount` points have been displayed. You'll learn more Graphics features in Chapter 15.

### Look-and-Feel Observation 14.14

Drawing on any GUI component is performed with coordinates that are measured from the upper-left corner (0, 0) of that GUI component, not the upper-left corner of the screen.

### Using the Custom `JPanel` in an Application

Class `Painter` (Fig. 14.35) contains the main method that executes this application. Line 14 creates a `PaintPanel` object on which the user can drag the mouse to draw. Line 15 attaches the `PaintPanel` to the `JFrame`.

```

1 // Fig. 14.35: Painter.java
2 // Testing PaintPanel.
3 import java.awt.BorderLayout;
4 import javax.swing.JFrame;
5 import javax.swing.JLabel;
6
7 public class Painter
8 {
9     public static void main( String[] args )
10    {
11        // create JFrame
12        JFrame application = new JFrame( "A simple paint program" );
13
14        PaintPanel paintPanel = new PaintPanel(); // create paint panel
15        application.add( paintPanel, BorderLayout.CENTER ); // in center
16
17        // create a label and place it in SOUTH of BorderLayout
18        application.add( new JLabel( "Drag the mouse to draw" ),
19                        BorderLayout.SOUTH );
20
21        application.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );

```

**Fig. 14.35** | Test class for `PaintPanel`. (Part I of 2.)

```

22     application.setSize( 400, 200 ); // set frame size
23     application.setVisible( true ); // display frame
24     } // end main
25 } // end class Painter

```

**Fig. 14.35** | Test class for PaintPane1. (Part 2 of 2.)

## 14.17 Key Event Handling

This section presents the `KeyListener` interface for handling **key events**. Key events are generated when keys on the keyboard are pressed and released. A class that implements `KeyListener` must provide declarations for methods **keyPressed**, **keyReleased** and **keyTyped**, each of which receives a `KeyEvent` as its argument. Class `KeyEvent` is a subclass of `InputEvent`. Method `keyPressed` is called in response to pressing any key. Method `keyTyped` is called in response to pressing any key that is not an **action key**. (The action keys are any arrow key, *Home*, *End*, *Page Up*, *Page Down*, any function key, etc.) Method `keyReleased` is called when the key is released after any `keyPressed` or `keyTyped` event.

The application of Figs. 14.36–14.37 demonstrates the `KeyListener` methods. Class `KeyDemoFrame` implements the `KeyListener` interface, so all three methods are declared in the application. The constructor (Fig. 14.36, lines 17–28) registers the application to handle its own key events by using method **addKeyListener** at line 27. Method `addKeyListener` is declared in class `Component`, so every subclass of `Component` can notify `KeyListener` objects of key events for that `Component`.

```

1 // Fig. 14.36: KeyDemoFrame.java
2 // Demonstrating keystroke events.
3 import java.awt.Color;
4 import java.awt.event.KeyListener;
5 import java.awt.event.KeyEvent;
6 import javax.swing.JFrame;
7 import javax.swing.JTextArea;
8
9 public class KeyDemoFrame extends JFrame implements KeyListener
10 {
11     private String line1 = ""; // first line of textarea
12     private String line2 = ""; // second line of textarea
13     private String line3 = ""; // third line of textarea
14     private JTextArea textarea; // textarea to display output
15

```

**Fig. 14.36** | Key event handling. (Part 1 of 2.)

```

16 // KeyDemoFrame constructor
17 public KeyDemoFrame()
18 {
19     super( "Demonstrating Keystroke Events" );
20
21     textArea = new JTextArea( 10, 15 ); // set up JTextArea
22     textArea.setText( "Press any key on the keyboard..." );
23     textArea.setEnabled( false ); // disable textarea
24     textArea.setDisabledTextColor( Color.BLACK ); // set text color
25     add( textArea ); // add textarea to JFrame
26
27     addKeyListener( this ); // allow frame to process key events
28 } // end KeyDemoFrame constructor
29
30 // handle press of any key
31 public void keyPressed( KeyEvent event )
32 {
33     line1 = String.format( "Key pressed: %s",
34         KeyEvent.getKeyText( event.getKeyCode() ) ); // show pressed key
35     setLines2and3( event ); // set output lines two and three
36 } // end method keyPressed
37
38 // handle release of any key
39 public void keyReleased( KeyEvent event )
40 {
41     line1 = String.format( "Key released: %s",
42         KeyEvent.getKeyText( event.getKeyCode() ) ); // show released key
43     setLines2and3( event ); // set output lines two and three
44 } // end method keyReleased
45
46 // handle press of an action key
47 public void keyTyped( KeyEvent event )
48 {
49     line1 = String.format( "Key typed: %s", event.getKeyChar() );
50     setLines2and3( event ); // set output lines two and three
51 } // end method keyTyped
52
53 // set second and third lines of output
54 private void setLines2and3( KeyEvent event )
55 {
56     line2 = String.format( "This key is %san action key",
57         ( event.isActionKey() ? "" : "not " ) );
58
59     String temp = KeyEvent.getKeyModifiersText( event.getModifiers() );
60
61     line3 = String.format( "Modifier keys pressed: %s",
62         ( temp.equals( "" ) ? "none" : temp ) ); // output modifiers
63
64     textArea.setText( String.format( "%s\n%s\n%s\n",
65         line1, line2, line3 ) ); // output three lines of text
66 } // end method setLines2and3
67 } // end class KeyDemoFrame

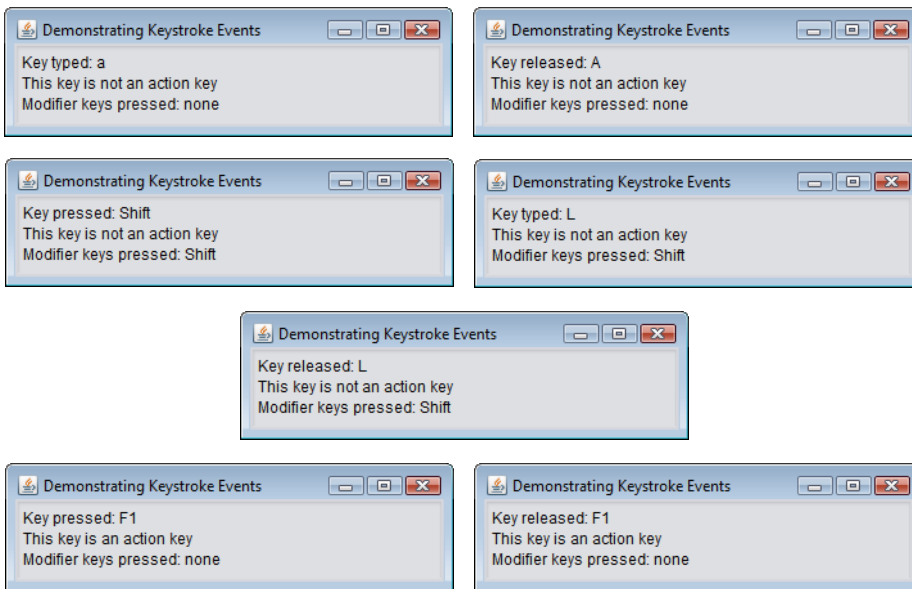

```

**Fig. 14.36** | Key event handling. (Part 2 of 2.)

```

1 // Fig. 14.37: KeyDemo.java
2 // Testing KeyDemoFrame.
3 import javax.swing.JFrame;
4
5 public class KeyDemo
6 {
7     public static void main( String[] args )
8     {
9         KeyDemoFrame keyDemoFrame = new KeyDemoFrame();
10        keyDemoFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        keyDemoFrame.setSize( 350, 100 ); // set frame size
12        keyDemoFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class KeyDemo

```

**Fig. 14.37** | Test class for KeyDemoFrame.

At line 25, the constructor adds the `JTextArea` `textArea` (where the application's output is displayed) to the `JFrame`. A `JTextArea` is a *multiline area* in which you can display text. (We discuss `JTextAreas` in more detail in Section 14.20.) Notice in the screen captures that `textArea` occupies the *entire window*. This is due to the `JFrame`'s default `BorderLayout` (discussed in Section 14.18.2 and demonstrated in Fig. 14.41). When a single `Component` is added to a `BorderLayout`, the `Component` occupies the entire `Container`. Line 23 disables the `JTextArea` so the user cannot type in it. This causes the text in the `JTextArea` to become gray. Line 24 uses method `setDisabledTextColor` to change the text color in the `JTextArea` to black for readability.

Methods `keyPressed` (lines 31–36) and `keyReleased` (lines 39–44) use `KeyEvent` method `getKeyCode` to get the **virtual key code** of the pressed key. Class `KeyEvent` contains virtual key-code constants that represent every key on the keyboard. These constants

can be compared with `getKeyCode`'s return value to test for individual keys on the keyboard. The value returned by `getKeyCode` is passed to static `KeyEvent` method **`getKeyText`**, which returns a string containing the name of the key that was pressed. For a complete list of virtual key constants, see the on-line documentation for class `KeyEvent` (package `java.awt.event`). Method `keyTyped` (lines 47–51) uses `KeyEvent` method **`getKeyChar`** (which returns a `char`) to get the Unicode value of the character typed.

All three event-handling methods finish by calling method `setLines2and3` (lines 54–66) and passing it the `KeyEvent` object. This method uses `KeyEvent` method **`isActionKey`** (line 57) to determine whether the key in the event was an action key. Also, `InputEvent` method **`getModifiers`** is called (line 59) to determine whether any modifier keys (such as *Shift*, *Alt* and *Ctrl*) were pressed when the key event occurred. The result of this method is passed to static `KeyEvent` method **`getKeyModifiersText`**, which produces a string containing the names of the pressed modifier keys.

[*Note:* If you need to test for a specific key on the keyboard, class `KeyEvent` provides a **key constant** for each one. These constants can be used from the key event handlers to determine whether a particular key was pressed. Also, to determine whether the *Alt*, *Ctrl*, *Meta* and *Shift* keys are pressed individually, `InputEvent` methods **`isAltDown`**, **`isControlDown`**, **`isMetaDown`** and **`isShiftDown`** each return a `boolean` indicating whether the particular key was pressed during the key event.]

## 14.18 Introduction to Layout Managers

**Layout managers** arrange GUI components in a container for presentation purposes. You can use the layout managers for basic layout capabilities instead of determining every GUI component's exact position and size. This functionality enables you to concentrate on the basic look-and-feel and lets the layout managers process most of the layout details. All layout managers implement the interface **`LayoutManager`** (in package `java.awt`). Class `Container`'s `setLayout` method takes an object that implements the `LayoutManager` interface as an argument. There are basically three ways for you to arrange components in a GUI:

1. *Absolute positioning:* This provides the greatest level of control over a GUI's appearance. By setting a `Container`'s layout to `null`, you can specify the absolute position of each GUI component with respect to the upper-left corner of the `Container` by using `Component` methods `setSize` and `setLocation` or `setBounds`. If you do this, you also must specify each GUI component's size. Programming a GUI with absolute positioning can be tedious, unless you have an integrated development environment (IDE) that can generate the code for you.
2. *Layout managers:* Using layout managers to position elements can be simpler and faster than creating a GUI with absolute positioning, but you lose some control over the size and the precise positioning of GUI components.
3. *Visual programming in an IDE:* IDEs provide tools that make it easy to create GUIs. Each IDE typically provides a **GUI design tool** that allows you to drag and drop GUI components from a tool box onto a design area. You can then position, size and align GUI components as you like. The IDE generates the Java code that creates the GUI. In addition, you can typically add event-handling code for a particular component by double-clicking the component. Some design tools also allow you to use the layout managers described in this chapter and in Chapter 25.

### Look-and-Feel Observation 14.15

Most Java IDEs provide GUI design tools for visually designing a GUI; the tools then write Java code that creates the GUI. Such tools often provide greater control over the size, position and alignment of GUI components than do the built-in layout managers.

### Look-and-Feel Observation 14.16

It's possible to set a Container's layout to `null`, which indicates that no layout manager should be used. In a Container without a layout manager, you must position and size the components in the given container and take care that, on resize events, all components are repositioned as necessary. A component's resize events can be processed by a `ComponentListener`.

Figure 14.38 summarizes the layout managers presented in this chapter. Others are discussed in Chapter 25, and the powerful `GridLayout` layout manager is discussed in Appendix I.

| Layout manager            | Description                                                                                                                                                                                                                                                                                                                         |
|---------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>FlowLayout</code>   | Default for <code>javax.swing.JPanel</code> . Places components sequentially (left to right) in the order they were added. It's also possible to specify the order of the components by using the <code>Container</code> method <code>add</code> , which takes a <code>Component</code> and an integer index position as arguments. |
| <code>BorderLayout</code> | Default for <code>JFrames</code> (and other windows). Arranges the components into five areas: NORTH, SOUTH, EAST, WEST and CENTER.                                                                                                                                                                                                 |
| <code>GridLayout</code>   | Arranges the components into rows and columns.                                                                                                                                                                                                                                                                                      |

**Fig. 14.38** | Layout managers.

## 14.18.1 `FlowLayout`

`FlowLayout` is the *simplest* layout manager. GUI components are placed on a container from left to right in the order in which they're added to the container. When the edge of the container is reached, components continue to display on the next line. Class `FlowLayout` allows GUI components to be *left aligned*, *centered* (the default) and *right aligned*.

The application of Figs. 14.39–14.40 creates three  `JButton`  objects and adds them to the application, using a `FlowLayout` layout manager. The components are center aligned by default. When the user clicks **Left**, the alignment for the layout manager is changed to a left-aligned `FlowLayout`. When the user clicks **Right**, the alignment for the layout manager is changed to a right-aligned `FlowLayout`. When the user clicks **Center**, the alignment for the layout manager is changed to a center-aligned `FlowLayout`. Each button has its own event handler that's declared with an anonymous inner class that implements `ActionListener`. The sample output windows show each of the `FlowLayout` alignments. Also, the last sample output window shows the centered alignment after the window has been resized to a smaller width. Notice that the button **Right** flows onto a new line.

As seen previously, a container's layout is set with method `setLayout` of class `Container`. Line 25 sets the layout manager to the `FlowLayout` declared at line 23. Normally, the layout is set before any GUI components are added to a container.

### Look-and-Feel Observation 14.17

*Each individual container can have only one layout manager, but multiple containers in the same application can each use different layout managers.*

```

8     {
9         FlowLayoutFrame flowLayoutFrame = new FlowLayoutFrame();
10        flowLayoutFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        flowLayoutFrame.setSize( 300, 75 ); // set frame size
12        flowLayoutFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class FlowLayoutDemo

```

---

**Fig. 14.40** | Test class for FlowLayoutFrame. (Part 1 of 2.)

**Fig. 14.40** | Test class for `FlowLayoutFrame`. (Part 2 of 2.)

Each button's event handler is specified with a separate anonymous inner-class object (Fig. 14.39, lines 30–43, 48–61 and 66–79, respectively), and method `actionPerformed` in each case executes two statements. For example, line 37 in the event handler for `LeftJButton` uses `FlowLayout` method **`setAlignment`** to change the alignment for the `FlowLayout` to a left-aligned (**`FlowLayout.LEFT`**) `FlowLayout`. Line 40 uses `LayoutManager` interface method **`layoutContainer`** (which is inherited by all layout managers) to specify that the `JFrame` should be rearranged based on the adjusted layout. According to which button was clicked, the `actionPerformed` method for each button sets the `FlowLayout`'s alignment to `FlowLayout.LEFT` (line 37), **`FlowLayout.CENTER`** (line 55) or **`FlowLayout.RIGHT`** (line 73).

### 14.18.2 BorderLayout

The `BorderLayout` layout manager (the default layout manager for a `JFrame`) arranges components into five regions: NORTH, SOUTH, EAST, WEST and CENTER. NORTH corresponds to the top of the container. Class `BorderLayout` extends `Object` and implements interface **`LayoutManager2`** (a subinterface of `LayoutManager` that adds several methods for enhanced layout processing).

A `BorderLayout` limits a `Container` to containing at most five components—one in each region. The component placed in each region can be a container to which other components are attached. The components placed in the NORTH and SOUTH regions extend horizontally to the sides of the container and are as tall as the components placed in those regions. The EAST and WEST regions expand vertically between the NORTH and SOUTH regions and are as wide as the components placed in those regions. The component placed in the CENTER region expands to fill all remaining space in the layout (which is the reason the `JTextArea` in Fig. 14.37 occupies the entire window). If all five regions are occupied, the entire container's space is covered by GUI components. If the NORTH or SOUTH region is not occupied, the GUI components in the EAST, CENTER and WEST regions expand vertically to fill the remaining space. If the EAST or WEST region is not occupied, the GUI component in the CENTER region expands horizontally to fill the remaining space. If the CENTER region is not occupied, the area is left empty—the other GUI components do *not* expand

to fill the remaining space. The application of Figs. 14.41–14.42 demonstrates the BorderLayout layout manager by using five JButtons.

```

1 // Fig. 14.41: BorderLayoutFrame.java
2 // Demonstrating BorderLayout.
3 import java.awt.BorderLayout;
4 import java.awt.event.ActionListener;
5 import java.awt.event.ActionEvent;
6 import javax.swing.JFrame;
7 import javax.swing.JButton;
8
9 public class BorderLayoutFrame extends JFrame implements ActionListener
10 {
11     private JButton[] buttons; // array of buttons to hide portions
12     private static final String[] names = { "Hide North", "Hide South",
13         "Hide East", "Hide West", "Hide Center" };
14     private BorderLayout layout; // borderlayout object
15
16     // set up GUI and event handling
17     public BorderLayoutFrame()
18     {
19         super( "BorderLayout Demo" );
20
21         layout = new BorderLayout( 5, 5 ); // 5 pixel gaps
22         setLayout( layout ); // set frame layout
23         buttons = new JButton[ names.length ]; // set size of array
24
25         // create JButtons and register listeners for them
26         for ( int count = 0; count < names.length; count++ )
27         {
28             buttons[ count ] = new JButton( names[ count ] );
29             buttons[ count ].addActionListener( this );
30         } // end for
31
32         add( buttons[ 0 ], BorderLayout.NORTH ); // add button to north
33         add( buttons[ 1 ], BorderLayout.SOUTH ); // add button to south
34         add( buttons[ 2 ], BorderLayout.EAST ); // add button to east
35         add( buttons[ 3 ], BorderLayout.WEST ); // add button to west
36         add( buttons[ 4 ], BorderLayout.CENTER ); // add button to center
37     } // end BorderLayoutFrame constructor
38
39     // handle button events
40     public void actionPerformed( ActionEvent event )
41     {
42         // check event source and lay out content pane correspondingly
43         for ( JButton button : buttons )
44         {
45             if ( event.getSource() == button )
46                 button.setVisible( false ); // hide button clicked
47             else
48                 button.setVisible( true ); // show other buttons
49         } // end for

```

**Fig. 14.41** | BorderLayout containing five buttons. (Part I of 2.)

```

50
51     layout.layoutContainer( getContentPane() ); // lay out content pane
52 } // end method actionPerformed
53 } // end class BorderLayoutFrame

```

**Fig. 14.41** | BorderLayout containing five buttons. (Part 2 of 2.)

```

1 // Fig. 14.42: BorderLayoutDemo.java
2 // Testing BorderLayoutFrame.
3 import javax.swing.JFrame;
4
5 public class BorderLayoutDemo
6 {
7     public static void main( String[] args )
8     {
9         BorderLayoutFrame borderLayoutFrame = new BorderLayoutFrame();
10        borderLayoutFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        borderLayoutFrame.setSize( 300, 200 ); // set frame size
12        borderLayoutFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class BorderLayoutDemo

```

**Fig. 14.42** | Test class for BorderLayoutFrame.

Line 21 of Fig. 14.41 creates a `BorderLayout`. The constructor arguments specify the number of pixels between components that are arranged horizontally (**horizontal gap space**) and between components that are arranged vertically (**vertical gap space**), respectively. The default is one pixel of gap space horizontally and vertically. Line 22 uses method `setLayout` to set the content pane's layout to `layout`.

We add Components to a `BorderLayout` with another version of `Container` method `add` that takes two arguments—the `Component` to add and the region in which the `Component` should appear. For example, line 32 specifies that `buttons[ 0 ]` should appear in the `NORTH` region. The components can be added in any order, but only one component should be added to each region.

### Look-and-Feel Observation 14.18

*If no region is specified when adding a `Component` to a `BorderLayout`, the layout manager assumes that the `Component` should be added to region `BorderLayout.CENTER`.*

### Common Programming Error 14.6

*When more than one component is added to a region in a `BorderLayout`, only the last component added to that region will be displayed. There's no error that indicates this problem.*

Class `BorderLayoutFrame` implements `ActionListener` directly in this example, so the `BorderLayoutFrame` will handle the events of the `JButtons`. For this reason, line 29 passes the `this` reference to the `addActionListener` method of each `JButton`. When the user clicks a particular `JButton` in the layout, method `actionPerformed` (lines 40–52) executes. The enhanced `for` statement at lines 43–49 uses an `if...else` to hide the particular `JButton` that generated the event. Method `setVisible` (inherited into `JButton` from class `Component`) is called with a `false` argument (line 46) to hide the `JButton`. If the current `JButton` in the array is not the one that generated the event, method `setVisible` is called with a `true` argument (line 48) to ensure that the `JButton` is displayed on the screen. Line 51 uses `LayoutManager` method `layoutContainer` to recalculate the layout of the content pane. Notice in the screen captures of Fig. 14.42 that certain regions in the `BorderLayout` change shape as `JButtons` are hidden and displayed in other regions. Try resizing the application window to see how the various regions resize based on the window's width and height. *For more complex layouts, group components in `JPanels`, each with a separate layout manager.* Place the `JPanels` on the `JFrame` using either the default `BorderLayout` or some other layout.

## 14.18.3 GridLayout

The **GridLayout** layout manager divides the container into a *grid* so that components can be placed in *rows* and *columns*. Class `GridLayout` inherits directly from class `Object` and implements interface `LayoutManager`. Every `Component` in a `GridLayout` has the *same* width and height. Components are added to a `GridLayout` starting at the top-left cell of the grid and proceeding left to right until the row is full. Then the process continues left to right on the next row of the grid, and so on. The application of Figs. 14.43–14.44 demonstrates the `GridLayout` layout manager by using six `JButtons`.

Lines 24–25 create two `GridLayout` objects. The `GridLayout` constructor used at line 24 specifies a `GridLayout` with 2 rows, 3 columns, 5 pixels of horizontal-gap space between Components in the grid and 5 pixels of vertical-gap space between Components in the grid.

```

1 // Fig. 14.43: GridLayoutFrame.java
2 // Demonstrating GridLayout.
3 import java.awt.GridLayout;
4 import java.awt.Container;
5 import java.awt.event.ActionListener;
6 import java.awt.event.ActionEvent;
7 import javax.swing.JFrame;
8 import javax.swing.JButton;
9
10 public class GridLayoutFrame extends JFrame implements ActionListener
11 {
12     private JButton[] buttons; // array of buttons
13     private static final String[] names =
14         { "one", "two", "three", "four", "five", "six" };
15     private boolean toggle = true; // toggle between two layouts
16     private Container container; // frame container
17     private GridLayout gridLayout1; // first gridlayout
18     private GridLayout gridLayout2; // second gridlayout
19
20     // no-argument constructor
21     public GridLayoutFrame()
22     {
23         super( "GridLayout Demo" );
24         gridLayout1 = new GridLayout( 2, 3, 5, 5 ); // 2 by 3; gaps of 5
25         gridLayout2 = new GridLayout( 3, 2 ); // 3 by 2; no gaps
26         container = getContentPane(); // get content pane
27         setLayout( gridLayout1 ); // set JFrame layout
28         buttons = new JButton[ names.length ]; // create array of JButtons
29
30         for ( int count = 0; count < names.length; count++ )
31         {
32             buttons[ count ] = new JButton( names[ count ] );
33             buttons[ count ].addActionListener( this ); // register listener
34             add( buttons[ count ] ); // add button to JFrame
35         } // end for
36     } // end GridLayoutFrame constructor
37
38     // handle button events by toggling between layouts
39     public void actionPerformed( ActionEvent event )
40     {
41         if ( toggle )
42             container.setLayout( gridLayout2 ); // set layout to second
43         else
44             container.setLayout( gridLayout1 ); // set layout to first
45
46         toggle = !toggle; // set toggle to opposite value
47         container.validate(); // re-lay out container
48     } // end method actionPerformed
49 } // end class GridLayoutFrame

```

**Fig. 14.43** | GridLayout containing six buttons.

The GridLayout constructor used at line 25 specifies a GridLayout with 3 rows and 2 columns that uses the default gap space (1 pixel).

```

1 // Fig. 14.44: GridLayoutDemo.java
2 // Testing GridLayoutFrame.
3 import javax.swing.JFrame;
4
5 public class GridLayoutDemo
6 {
7     public static void main( String[] args )
8     {
9         GridLayoutFrame gridLayoutFrame = new GridLayoutFrame();
10        gridLayoutFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        gridLayoutFrame.setSize( 300, 200 ); // set frame size
12        gridLayoutFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class GridLayoutDemo

```

**Fig. 14.44** | Test class for GridLayoutFrame.

The JButton objects in this example initially are arranged using `gridLayout1` (set for the content pane at line 27 with method `setLayout`). The first component is added to the first column of the first row. The next component is added to the second column of the first row, and so on. When a JButton is pressed, method `actionPerformed` (lines 39–48) is called. Every call to `actionPerformed` toggles the layout between `gridLayout2` and `gridLayout1`, using boolean variable `toggle` to determine the next layout to set.

Line 47 shows another way to reformat a container for which the layout has changed. Container method `validate` recomputes the container's layout based on the current layout manager for the Container and the current set of displayed GUI components.

## 14.19 Using Panels to Manage More Complex Layouts

Complex GUIs (like Fig. 14.1) require that each component be placed in an exact location. They often consist of multiple panels, with each panel's components arranged in a specific layout. Class `JPanel` extends `JComponent` and `JComponent` extends class `Container`, so every `JPanel` is a `Container`. Thus, every `JPanel` may have components, including other panels, attached to it with `Container` method `add`. The application of Figs. 14.45–14.46 demonstrates how a `JPanel` can be used to create a more complex layout in which several JButtons are placed in the SOUTH region of a `BorderLayout`.

After `JPanel` `buttonJPanel` is declared (line 11) and created (line 19), line 20 sets `buttonJPanel`'s layout to a `GridLayout` of one row and five columns (there are five JButtons in array `buttons`). Lines 23–27 add the JButtons in the array to the `JPanel`. Line 26 adds the buttons directly to the `JPanel`—class `JPanel` does not have a content pane, unlike a `JFrame`. Line 29 uses the `JFrame`'s default `BorderLayout` to add `buttonJPanel` to the SOUTH region. The SOUTH region is as tall as the buttons on `buttonJPanel`. A `JPanel` is sized

to the components it contains. As more components are added, the JPanel grows (according to the restrictions of its layout manager) to accommodate the components. Resize the window to see how the layout manager affects the size of the JButtons.

---

```

1 // Fig. 14.45: PanelFrame.java
2 // Using a JPanel to help lay out components.

## 14.20 JTextArea

A **JTextArea** provides an area for *manipulating multiple lines of text*. Like class **JTextField**, **JTextArea** is a subclass of **JTextComponent**, which declares common methods for **JTextFields**, **JTextAreas** and several other text-based GUI components.

The application in Figs. 14.47–14.48 demonstrates **JTextAreas**. One **JTextArea** displays text that the user can select. The other is uneditable and is used to display the text the user selected in the first **JTextArea**. Unlike **JTextFields**, **JTextAreas** do not have action events—when you press *Enter* while typing in a **JTextArea**, the cursor simply moves to the next line. As with multiple-selection **JLists** (Section 14.13), an external event from another GUI component indicates when to process the text in a **JTextArea**. For example, when typing an e-mail message, you normally click a **Send** button to send the text of the message to the recipient. Similarly, when editing a document in a word processor, you normally save the file by selecting a **Save** or **Save As...** menu item. In this program, the button **Copy >>>** generates the external event that copies the selected text in the left **JTextArea** and displays it in the right **JTextArea**.

```

1 // Fig. 14.47: TextAreaFrame.java
2 // Copying selected text from one textarea to another.
3 import java.awt.event.ActionListener;
4 import java.awt.event.ActionEvent;
5 import javax.swing.Box;
6 import javax.swing.JFrame;
7 import javax.swing.JTextArea;
8 import javax.swing.JButton;
9 import javax.swing.JScrollPane;
10
11 public class TextAreaFrame extends JFrame
12 {
13     private JTextArea textArea1; // displays demo string
14     private JTextArea textArea2; // highlighted text is copied here
15     private JButton copyJButton; // initiates copying of text
16

```

**Fig. 14.47** | Copying selected text from one JTextArea to another. (Part 1 of 2.)

```

17 // no-argument constructor
18 public TextAreaFrame()
19 {
20     super( "TextArea Demo" );
21     Box box = Box.createHorizontalBox(); // create box
22     String demo = "This is a demo string to\n" +
23         "illustrate copying text\nfrom one textarea to \n" +
24         "another textarea using an\nexternal event\n";
25
26     textArea1 = new JTextArea( demo, 10, 15 ); // create textArea1
27     box.add( new JScrollPane( textArea1 ) ); // add scrollpane
28
29     copyJButton = new JButton( "Copy >>>" ); // create copy button
30     box.add( copyJButton ); // add copy button to box
31     copyJButton.addActionListener(
32
33         new ActionListener() // anonymous inner class
34         {
35             // set text in textArea2 to selected text from textArea1
36             public void actionPerformed( ActionEvent event )
37             {
38                 textArea2.setText( textArea1.getSelectedText() );
39             } // end method actionPerformed
40         } // end anonymous inner class
41     ); // end call to addActionListener
42
43     textArea2 = new JTextArea( 10, 15 ); // create second textarea
44     textArea2.setEditable( false ); // disable editing
45     box.add( new JScrollPane( textArea2 ) ); // add scrollpane
46
47     add( box ); // add box to frame
48 } // end TextAreaFrame constructor
49 } // end class TextAreaFrame

```

**Fig. 14.47** | Copying selected text from one JTextArea to another. (Part 2 of 2.)

```

1 // Fig. 14.48: TextAreaDemo.java
2 // Copying selected text from one textarea to another.
3 import javax.swing.JFrame;
4
5 public class TextAreaDemo
6 {
7     public static void main( String[] args )
8     {
9         TextAreaFrame textAreaFrame = new TextAreaFrame();
10        textAreaFrame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
11        textAreaFrame.setSize( 425, 200 ); // set frame size
12        textAreaFrame.setVisible( true ); // display frame
13    } // end main
14 } // end class TextAreaDemo

```

**Fig. 14.48** | Test class for TextAreaFrame. (Part 1 of 2.)

**Fig. 14.48** | Test class for TextAreaFrame. (Part 2 of 2.)

In the constructor (lines 18–48), line 21 creates a **Box** container (package `javax.swing`) to organize the GUI components. `Box` is a subclass of `Container` that uses a **BoxLayout** layout manager (discussed in detail in Section 25.9) to arrange the GUI components either horizontally or vertically. `Box`'s static method `createHorizontalBox` creates a `Box` that arranges components from left to right in the order that they're attached.

Lines 26 and 43 create `JTextAreas` `textArea1` and `textArea2`. Line 26 uses `JTextArea`'s three-argument constructor, which takes a `String` representing the initial text and two `ints` specifying that the `JTextArea` has 10 rows and 15 columns. Line 43 uses `JTextArea`'s two-argument constructor, specifying that the `JTextArea` has 10 rows and 15 columns. Line 26 specifies that `demo` should be displayed as the default `JTextArea` content. A `JTextArea` does not provide scrollbars if it cannot display its complete contents. So, line 27 creates a `JScrollPane` object, initializes it with `textArea1` and attaches it to container `box`. By default, horizontal and vertical scrollbars appear as necessary in a `JScrollPane`.

Lines 29–41 create `JButton` object `copyJButton` with the label "Copy >>>", add `copyJButton` to container `box` and register the event handler for `copyJButton`'s `ActionEvent`. This button provides the external event that determines when the program should copy the selected text in `textArea1` to `textArea2`. When the user clicks `copyJButton`, line 38 in `actionPerformed` indicates that method `getSelectedText` (inherited into `JTextArea` from `JTextComponent`) should return the selected text from `textArea1`. The user selects text by dragging the mouse over the desired text to highlight it. Method `setText` changes the text in `textArea2` to the string returned by `getSelectedText`.

Lines 43–45 create `textArea2`, set its `editable` property to `false` and add it to container `box`. Line 47 adds `box` to the `JFrame`. Recall from Section 14.18 that the default layout of a `JFrame` is a `BorderLayout` and that the `add` method by default attaches its argument to the `CENTER` of the `BorderLayout`.

When text reaches the right edge of a `JTextArea` the text can wrap to the next line. This is referred to as **line wrapping**. By default, `JTextArea` does *not* wrap lines.

#### Look-and-Feel Observation 14.19

To provide line wrapping functionality for a `JTextArea`, invoke `JTextArea` method `setLineWrap` with a true argument.

#### *JScrollPane* Scrollbar Policies

This example uses a `JScrollPane` to provide scrolling for a `JTextArea`. By default, `JScrollPane` displays scrollbars only if they're required. You can set the horizontal and vertical **scrollbar policies** of a `JScrollPane` when it's constructed. If a program has a ref-

reference to a `JScrollPane`, the program can use `JScrollPane` methods `setHorizontalScrollBarPolicy` and `setVerticalScrollBarPolicy` to change the scrollbar policies at any time. Class `JScrollPane` declares the constants

```
JScrollPane.VERTICAL_SCROLLBAR_ALWAYS
JScrollPane.HORIZONTAL_SCROLLBAR_ALWAYS
```

to indicate that *a scrollbar should always appear*, constants

```
JScrollPane.VERTICAL_SCROLLBAR_AS_NEEDED
JScrollPane.HORIZONTAL_SCROLLBAR_AS_NEEDED
```

to indicate that *a scrollbar should appear only if necessary* (the defaults) and constants

```
JScrollPane.VERTICAL_SCROLLBAR_NEVER
JScrollPane.HORIZONTAL_SCROLLBAR_NEVER
```

to indicate that *a scrollbar should never appear*. If the horizontal scrollbar policy is set to `JScrollPane.HORIZONTAL_SCROLLBAR_NEVER`, a `JTextArea` attached to the `JScrollPane` will automatically wrap lines.

## 14.21 Wrap-Up

In this chapter, you learned many GUI components and how to implement event handling. You also learned about nested classes, inner classes and anonymous inner classes. You saw the special relationship between an inner-class object and an object of its top-level class. You learned how to use `JOptionPane` dialogs to obtain text input from the user and how to display messages to the user. You also learned how to create applications that execute in their own windows. We discussed class `JFrame` and components that enable a user to interact with an application. We also showed you how to display text and images to the user. You learned how to customize `JPanels` to create custom drawing areas, which you'll use extensively in the next chapter. You saw how to organize components on a window using layout managers and how to creating more complex GUIs by using `JPanels` to organize components. Finally, you learned about the `JTextArea` component in which a user can enter text and an application can display text. In Chapter 25, you'll learn about more advanced GUI components, such as sliders, menus and more complex layout managers. In the next chapter, you'll learn how to add graphics to your GUI application. Graphics allow you to draw shapes and text with colors and styles.

## Summary

### Section 14.1 Introduction

- A graphical user interface (GUI; p. 550) presents a user-friendly mechanism for interacting with an application. A GUI gives an application a distinctive look and feel (p. 555).
- Providing different applications with consistent, intuitive user-interface components gives users a sense of familiarity with a new application, so that they can learn it more quickly.
- GUIs are built from GUI components (p. 550)—sometimes called controls or widgets.

### Section 14.2 Java's New Nimbus Look-and-Feel

- As of Java SE 6 update 10, Java comes bundled with a new, elegant, cross-platform look-and-feel known as Nimbus (p. 551).

- To set Nimbus as the default for all Java applications, create a `swing.properties` text file in the `lib` folder of your JDK and JRE installation folders. Place the following line of code in the file:
 

```
swing.defaultlaf=com.sun.java.swing.plaf.nimbus.NimbusLookAndFeel
```
- To select Nimbus on an application-by-application basis, place the following command-line argument after the `java` command and before the application's name when you run the application:
 

```
-Dswing.defaultlaf=com.sun.java.swing.plaf.nimbus.NimbusLookAndFeel
```

### *Section 14.3 Simple GUI-Based Input/Output with JOptionPane*

- Most applications use windows or dialog boxes (p. 552) to interact with the user.
- Class `JOptionPane` (p. 552) of package `javax.swing` (p. 550) provides prebuilt dialog boxes for both input and output. `JOptionPane` static method `showInputDialog` (p. 553) displays an input dialog (p. 552).
- A prompt typically uses sentence-style capitalization—capitalizing only the first letter of the first word in the text unless the word is a proper noun.
- An input dialog can input only input `Strings`. This is typical of most GUI components.
- `JOptionPane` static method `showMessageDialog` (p. 554) displays a message dialog (p. 552).

### *Section 14.4 Overview of Swing Components*

- Most Swing GUI components (p. 550) are located in package `javax.swing`.
- Together, the appearance and the way in which the user interacts with the application are known as that application's look-and-feel. Swing GUI components allow you to specify a uniform look-and-feel for your application across all platforms or to use each platform's custom look-and-feel.
- Lightweight Swing components are not tied to actual GUI components supported by the underlying platform on which an application executes.
- Several Swing components are heavyweight components (p. 556) that require direct interaction with the local windowing system (p. 556), which may restrict their appearance and functionality.
- Class `Component` (p. 556; package `java.awt`) declares many of the attributes and behaviors common to the GUI components in packages `java.awt` (p. 555) and `javax.swing`.
- Class `Container` (p. 556; package `java.awt`) is a subclass of `Component`. Components are attached to Containers so the Components can be organized and displayed on the screen.
- Class `JComponent` (p. 556) of package `javax.swing` is a subclass of `Container`. `JComponent` is the superclass of all lightweight Swing components and declares their common attributes and behaviors.
- Some common `JComponent` features include a pluggable look-and-feel (p. 556), shortcut keys called mnemonics (p. 556), tool tips (p. 556), support for assistive technologies and support for user-interface localization (p. 556).

### *Section 14.5 Displaying Text and Images in a Window*

- Class `JFrame` provides the basic attributes and behaviors of a window.
- A `JLabel` (p. 557) displays read-only text, an image, or both text and an image. Text in a `JLabel` normally uses sentence-style capitalization.
- Each GUI component must be attached to a container, such as a window created with a `JFrame` (p. 559).
- Many IDEs provide GUI design tools (p. 604) in which you can specify the exact size and location of a component by using the mouse; then the IDE will generate the GUI code for you.
- `JComponent` method `setToolTipText` (p. 559) specifies the tool tip that's displayed when the user positions the mouse cursor over a lightweight component (p. 556).

- Container method `add` attaches a GUI component to a Container.
- Class `ImageIcon` (p. 560) supports several image formats, including GIF, PNG and JPEG.
- Method `getClass` of class `Object` (p. 560) retrieves a reference to the `Class` object that represents the the class declaration for the object on which the method is called.
- Class method `getResource` (p. 560) returns the location of its argument as a URL. The method `getResource` uses the `Class` object's class loader to determine the location of the resource.
- The horizontal and vertical alignments of a `JLabel` can be set with methods `setHorizontalAlignment` (p. 560) and `setVerticalAlignment` (p. 560), respectively.
- `JLabel` methods `setText` (p. 560) and `getText` (p. 560) set and get the text displayed on a label.
- `JLabel` methods `setIcon` (p. 560) and `getIcon` (p. 560) set and get the `Icon` (p. 560) on a label.
- `JLabel` methods `setHorizontalTextPosition` (p. 560) and `setVerticalTextPosition` (p. 560) specify the text position in the label.
- `JFrame` method `setDefaultCloseOperation` (p. 561) with constant `JFrame.EXIT_ON_CLOSE` as the argument indicates that the program should terminate when the window is closed by the user.
- Component method `setSize` (p. 561) specifies the width and height of a component.
- Component method `setVisible` (p. 561) with the argument `true` displays a `JFrame` on the screen.

### *Section 14.6 Text Fields and an Introduction to Event Handling with Nested Classes*

- GUIs are event driven—when the user interacts with a GUI component, events (p. 561) drive the program to perform tasks.
- An event handler (p. 561) performs a task in response to an event.
- Class `JTextField` (p. 561) extends `JTextComponent` (p. 561) of package `javax.swing.text`, which provides common text-based component features. Class `JPasswordField` (p. 561) extends `JTextField` and adds several methods that are specific to processing passwords.
- A `JPasswordField` (p. 561) shows that characters are being typed as the user enters them, but hides the actual characters with echo characters (p. 562).
- A component receives the focus (p. 562) when the user clicks the component.
- `JTextComponent` method `setEditable` (p. 564) can be used to make a text field uneditable.
- To respond to an event for a particular GUI component, you must create a class that represents the event handler and implements an appropriate event-listener interface (p. 564), then register an object of the event-handling class as the event handler (p. 564).
- Non-static nested classes (p. 564) are called inner classes and are frequently used for event handling.
- An object of a non-static inner class (p. 564) must be created by an object of the top-level class (p. 564) that contains the inner class.
- An inner-class object can directly access the instance variables and methods of its top-level class.
- A nested class that's `static` does not require an object of its top-level class and does not implicitly have a reference to an object of the top-level class.
- Pressing *Enter* in a `JTextField` (p. 561) or `JPasswordField` generates an `ActionEvent` (p. 565) from package `java.awt.event` (p. 567) that can be handled by an `ActionListener` (p. 565; package `java.awt.event`).
- `JTextField` method `addActionListener` (p. 565) registers an event handler for a text field's `ActionEvent`.
- The GUI component with which the user interacts is the event source (p. 566).

- An `ActionEvent` object contains information about the event that just occurred, such as the event source and the text in the text field.
- `ActionEvent` method `getSource` returns a reference to the event source. `ActionEvent` method `getActionCommand` (p. 566) returns the text the user typed in a text field or the label on a `JButton`.
- `JPasswordField` method `getPassword` (p. 566) returns the password the user typed.

### *Section 14.7 Common GUI Event Types and Listener Interfaces*

- Each event-object type typically has a corresponding event-listener interface that specifies one or more event-handling methods which must be declared in the class that implements the interface.

### *Section 14.8 How Event Handling Works*

- When an event occurs, the GUI component with which the user interacted notifies its registered listeners by calling each listener's appropriate event-handling method.
- Every GUI component supports several event types. When an event occurs, the event is dispatched (p. 570) only to the event listeners of the appropriate type.

### *Section 14.9 JButton*

- A button is a component the user clicks to trigger an action. All the button types are subclasses of `AbstractButton` (p. 571; package `javax.swing`). Button labels (p. 571) typically use book-title capitalization (p. 554).
- Command buttons (p. 571) are created with class `JButton`.
- A `JButton` can display an `Icon`. A `JButton` can also have a rollover `Icon` (p. 571)—an `Icon` that's displayed when the user positions the mouse over the button.
- Method `setRolloverIcon` (p. 573) of class `AbstractButton` specifies the image displayed on a button when the user positions the mouse over it.

### *Section 14.10 Buttons That Maintain State*

- There are three Swing state button types—`JToggleButton` (p. 574), `JCheckBox` (p. 574) and `JRadioButton` (p. 574).
- Classes `JCheckBox` and `JRadioButton` are subclasses of `JToggleButton`.
- Component method `setFont` (p. 576) sets the component's font to a new `Font` object (p. 576; package `java.awt`).
- Clicking a `JCheckBox` causes an `ItemEvent` (p. 576) that can be handled by an `ItemListener` (p. 576) which defines method `itemStateChanged` (p. 576). Method `addItemListener` registers the listener for the `ItemEvent` of a `JCheckBox` or `JRadioButton` object.
- `JCheckBox` method `isSelected` determines whether a `JCheckBox` is selected.
- `JRadioButtons` have two states—selected and not selected. Radio buttons (p. 571) normally appear as a group (p. 577) in which only one button can be selected at a time.
- `JRadioButtons` are used to represent mutually exclusive options (p. 577).
- The logical relationship between `JRadioButtons` is maintained by a `ButtonGroup` object (p. 577).
- `ButtonGroup` method `add` (p. 580) associates each `JRadioButton` with a `ButtonGroup`. If more than one selected `JRadioButton` object is added to a group, the selected one that was added first will be selected when the GUI is displayed.
- `JRadioButtons` generate `ItemEvents` when they're clicked.

### *Section 14.11 JComboBox and Using an Anonymous Inner Class for Event Handling*

- A `JComboBox` (p. 580) provides a list of items from which the user can make a single selection. `JComboBoxes` generate `ItemEvents`.

- Each item in a JComboBox has an index (p. 582). The first item added to a JComboBox appears as the currently selected item when the JComboBox is displayed.
- JComboBox method `setMaximumRowCount` (p. 583) sets the maximum number of elements that are displayed when the user clicks the JComboBox.
- An anonymous inner class (p. 583) is an inner class without a name and typically appears inside a method declaration. One object of the anonymous inner class must be created when the class is declared.
- JComboBox method `getSelectedIndex` (p. 583) returns the index of the selected item.

### Section 14.12 JList

- A JList displays a series of items from which the user may select one or more items. Class JList supports single-selection lists (p. 584) and multiple-selection lists.
- When the user clicks an item in a JList, a `ListSelectionEvent` (p. 584) occurs. JList method `addListSelectionListener` (p. 586) registers a `ListSelectionListener` (p. 586) for a JList's selection events. A `ListSelectionListener` of package `javax.swing.event` (p. 567) must implement method `valueChanged`.
- JList method `setVisibleRowCount` (p. 586) specifies the number of visible items in the list.
- JList method `setSelectionMode` (p. 586) specifies a list's selection mode (p. 586).
- A JList can be attached to a `JScrollPane` (p. 586) to provide a scrollbar (p. 583) for the JList.
- `JFrame` method `getContentPane` (p. 586) returns a reference to the `JFrame`'s content pane where GUI components are displayed.
- JList method `getSelectedIndex` (p. 586) returns the selected item's index.

### Section 14.13 Multiple-Selection Lists

- A multiple-selection list (p. 584) enables the user to select many items from a JList.
- JList method `setFixedCellWidth` (p. 588) sets a JList's width. Method `setFixedCellHeight` (p. 588) sets the height of each item in a JList.
- Normally, an external event (p. 588) generated by another GUI component (such as a `JButton`) specifies when the multiple selections in a JList should be processed.
- JList method `setListData` (p. 589) sets the items displayed in a JList. JList method `getSelectedValues` (p. 589) returns an array of `Object`s representing the selected items in a JList.

### Section 14.14 Mouse Event Handling

- The `MouseListener` (p. 570) and `MouseMotionListener` (p. 589) event-listener interfaces are used to handle mouse events (p. 570). Mouse events can be trapped for any GUI component that extends `Component`.
- Interface `MouseEvent` (p. 589) of package `javax.swing.event` extends interfaces `MouseListener` and `MouseMotionListener` to create a single interface containing all their methods.
- Each mouse event-handling method receives a `MouseEvent` object (p. 570) that contains information about the event, including the *x*- and *y*-coordinates where the event occurred. Coordinates are measured from the upper-left corner of the GUI component on which the event occurred.
- The methods and constants of class `InputEvent` (p. 589; `MouseEvent`'s superclass) enable an application to determine which mouse button the user clicked.
- Interface `MouseWheelListener` (p. 590) enables applications to respond to the rotation of a mouse wheel.

### Section 14.15 Adapter Classes

- An adapter class (p. 594) implements an interface and provides default implementations of its methods. When you extend an adapter class, you can override just the method(s) you need.
- `MouseEvent` method `getClickCount` (p. 597) returns the number of consecutive mouse-button clicks. Methods `isMetaDown` (p. 604) and `isAltDown` (p. 597) determine which mouse button the user clicked.

### Section 14.16 `JPanel` Subclass for Drawing with the Mouse

- `JComponent`'s method `paintComponent` (p. 597) is called when a lightweight Swing component is displayed. Override this method to specify how to draw shapes using Java's graphics capabilities.
- When overriding `paintComponent`, call the superclass version as the first statement in the body.
- Subclasses of `JComponent` support transparency. When a component is opaque (p. 597), `paintComponent` clears its background before the component is displayed.
- The transparency of a Swing lightweight component can be set with method `setOpaque` (p. 597); a `false` argument indicates that the component is transparent).
- Class `Point` (p. 599) package `java.awt` represents an *x-y* coordinate.
- Class `Graphics` (p. 599) is used to draw.
- `MouseEvent` method `getPoint` (p. 599) obtains the `Point` where a mouse event occurred.
- Method `repaint` (p. 599), inherited indirectly from class `Component`, indicates that a component should be refreshed on the screen as soon as possible.
- Method `paintComponent` receives a `Graphics` parameter and is called automatically whenever a lightweight component needs to be displayed on the screen.
- `Graphics` method `fillOval` (p. 600) draws a solid oval. The first two arguments are the upper-left *x-y* coordinate of the bounding box, and the last two are the bounding box's width and height.

### Section 14.17 Key Event Handling

- Interface `KeyListener` (p. 570) is used to handle key events (p. 570) that are generated when keys on the keyboard are pressed and released. Method `addKeyListener` of class `Component` (p. 601) registers a `KeyListener`.
- `KeyEvent` (p. 570) method `getKeyCode` (p. 603) gets the virtual key code (p. 603) of the key that was pressed. Class `KeyEvent` maintains a set of virtual key-code constants that represent every key on the keyboard.
- `KeyEvent` method `getKeyText` (p. 604) returns a string containing the name of the key that was pressed.
- `KeyEvent` method `getKeyChar` (p. 604) gets the Unicode value of the character typed.
- `KeyEvent` method `isActionKey` (p. 604) determines whether the key in an event was an action key (p. 601).
- `InputEvent` method `getModifiers` (p. 604) determines whether any modifier keys (such as *Shift*, *Alt* and *Ctrl*) were pressed when the key event occurred.
- `KeyEvent` method `getKeyModifiersText` (p. 604) returns a string containing the pressed modifier keys.

### Section 14.18 Introduction to Layout Managers

- Layout managers (p. 559) arrange GUI components in a container for presentation purposes.
- All layout managers implement the interface `LayoutManager` (p. 604) of package `java.awt`.
- Container method `setLayout` (p. 559) specifies the layout of a container.

- `FlowLayout` (p. 559) places components left to right in the order in which they're added to the container. When the container's edge is reached, components continue to display on the next line. `FlowLayout` allows GUI components to be left aligned, centered (the default) and right aligned.
- `FlowLayout` method `setAlignment` (p. 608) changes the alignment for a `FlowLayout`.
- `BorderLayout` (p. 592) the default for a `JFrame`) arranges components into five regions: NORTH, SOUTH, EAST, WEST and CENTER. NORTH corresponds to the top of the container.
- A `BorderLayout` limits a `Container` to containing at most five components—one in each region.
- `GridLayout` (p. 611) divides a container into a grid of rows and columns.
- `Container` method `validate` (p. 613) recomputes a container's layout based on the current layout manager for the `Container` and the current set of displayed GUI components.

### Section 14.19 Using Panels to Manage More Complex Layouts

- Complex GUIs often consist of multiple panels with different layouts. Every `JPanel` may have components, including other panels, attached to it with `Container` method `add`.

### Section 14.20 JTextArea

- A `JTextArea` (p. 615) may contain multiple lines of text. `JTextArea` is a subclass of `JTextComponent`.
- Class `Box` (p. 617) is a subclass of `Container` that uses a `BoxLayout` layout manager (p. 617) to arrange the GUI components either horizontally or vertically.
- `Box` static method `createHorizontalBox` (p. 617) creates a `Box` that arranges components from left to right in the order that they're attached.
- Method `getSelectedText` (p. 617) returns the selected text from a `JTextArea`.
- You can set the horizontal and vertical scrollbar policies (p. 617) of a `JScrollPane` when it's constructed. `JScrollPane` methods `setHorizontalScrollBarPolicy` (p. 618), and `setVerticalScrollBarPolicy` (p. 618) can be used to change the scrollbar policies at any time.

## Self-Review Exercises

- 14.1** Fill in the blanks in each of the following statements:
- Method \_\_\_\_\_ is called when the mouse is moved with no buttons pressed and an event listener is registered to handle the event.
  - Text that cannot be modified by the user is called \_\_\_\_\_ text.
  - A(n) \_\_\_\_\_ arranges GUI components in a `Container`.
  - The add method for attaching GUI components is a method of class \_\_\_\_\_.
  - GUI is an acronym for \_\_\_\_\_.
  - Method \_\_\_\_\_ is used to specify the layout manager for a container.
  - A `mouseDragged` method call is preceded by a(n) \_\_\_\_\_ method call and followed by a(n) \_\_\_\_\_ method call.
  - Class \_\_\_\_\_ contains methods that display message dialogs and input dialogs.
  - An input dialog capable of receiving input from the user is displayed with method \_\_\_\_\_ of class \_\_\_\_\_.
  - A dialog capable of displaying a message to the user is displayed with method of class \_\_\_\_\_.
  - Both `JTextField`s and `JTextAreas` directly extend class \_\_\_\_\_.
- 14.2** Determine whether each statement is *true* or *false*. If *false*, explain why.
- `BorderLayout` is the default layout manager for a `JFrame`'s content pane.
  - When the mouse cursor is moved into the bounds of a GUI component, method `mouseOver` is called.
  - A `JPanel` cannot be added to another `JPanel`.

- d) In a BorderLayout, two buttons added to the NORTH region will be placed side by side.
- e) A maximum of five components can be added to a BorderLayout.
- f) Inner classes are not allowed to access the members of the enclosing class.
- g) A JTextArea's text is always read-only.
- h) Class JTextArea is a direct subclass of class Component.

**14.3** Find the error(s) in each of the following statements, and explain how to correct it (them):

- a) `buttonName = JButton( "Caption" );`
- b) `JLabel aLabel, JLabel; // create references`
- c) `txtField = new JTextField( 50, "Default Text" );`
- d) `setLayout( new BorderLayout() );`  
`button1 = new JButton( "North Star" );`  
`button2 = new JButton( "South Pole" );`  
`add( button1 );`  
`add( button2 );`

## Answers to Self-Review Exercises

**14.1** a) mouseMoved. b) uneditable (read-only). c) layout manager. d) Container. e) graphical user interface. f) setLayout. g) mousePressed, mouseReleased. h) JOptionPane. i) showInputDialog, JOptionPane. j) showMessageDialog, JOptionPane. k) JTextComponent.

- 14.2**
- a) True.
  - b) False. Method mouseEntered is called.
  - c) False. A JPanel can be added to another JPanel, because JPanel is an indirect subclass of Component. So, a JPanel is a Component. Any Component can be added to a Container.
  - d) False. Only the last button added will be displayed. Remember that only one component should be added to each region in a BorderLayout.
  - e) True. [*Note:* Panels containing multiple components can be added to each region.]
  - f) False. Inner classes have access to all members of the enclosing class declaration.
  - g) False. JTextAreas are editable by default.
  - h) False. JTextArea derives from class JTextComponent.

- 14.3**
- a) new is needed to create an object.
  - b) JLabel is a class name and cannot be used as a variable name.
  - c) The arguments passed to the constructor are reversed. The String must be passed first.
  - d) BorderLayout has been set, and components are being added without specifying the region, so both are added to the center region. Proper add statements might be  
`add( button1, BorderLayout.NORTH );`  
`add( button2, BorderLayout.SOUTH );`

## Exercises

**14.4** Fill in the blanks in each of the following statements:

- a) The JTextField class directly extends class \_\_\_\_\_.
- b) Container method \_\_\_\_\_ attaches a GUI component to a container.
- c) Method \_\_\_\_\_ is called when a mouse button is released (without moving the mouse).
- d) The \_\_\_\_\_ class is used to create a group of JRadioButtons.

**14.5** Determine whether each statement is *true* or *false*. If *false*, explain why.

- a) Only one layout manager can be used per Container.
- b) GUI components can be added to a Container in any order in a BorderLayout.
- c) JRadioButtons provide a series of mutually exclusive options (i.e., only one can be true at a time).

- d) Graphics method `setFont` is used to set the font for text fields.
- e) A `JList` displays a scrollbar if there are more items in the list than can be displayed.
- f) A `Mouse` object has a method called `mouseDragged`.

**14.6** Determine whether each statement is *true* or *false*. If *false*, explain why.

- a) A `JPanel` is a `JComponent`.
- b) A `JPanel` is a `Component`.
- c) A `JLabel` is a `Container`.
- d) A `JList` is a `JPanel`.
- e) An `AbstractButton` is a `JButton`.
- f) A `TextField` is an `Object`.
- g) `ButtonGroup` is a subclass of `JComponent`.

**14.7** Find any errors in each of the following lines of code, and explain how to correct them.

- a) `import javax.swing.JFrame`
- b) `pane1Object.GridLayout( 8, 8 ); // set GridLayout`
- c) `container.setLayout( new FlowLayout( FlowLayout.DEFAULT ) );`
- d) `container.add( eastButton, EAST ); // BorderLayout`

**14.8** Create the following GUI. You do not have to provide any functionality.

**14.9** Create the following GUI. You do not have to provide any functionality.

**14.10** Create the following GUI. You do not have to provide any functionality.

**14.11** Create the following GUI. You do not have to provide any functionality.

**14.12 (Temperature Conversion)** Write a temperature-conversion application that converts from Fahrenheit to Celsius. The Fahrenheit temperature should be entered from the keyboard (via a `JTextField`). A `JLabel` should be used to display the converted temperature. Use the following formula for the conversion:

$$\text{Celsius} = \frac{5}{9} \times (\text{Fahrenheit} - 32)$$

**14.13 (Temperature-Conversion Modification)** Enhance the temperature-conversion application of Exercise 14.12 by adding the Kelvin temperature scale. The application should also allow the user to make conversions between any two scales. Use the following formula for the conversion between Kelvin and Celsius (in addition to the formula in Exercise 14.12):

$$\text{Kelvin} = \text{Celsius} + 273.15$$

**14.14 (Guess-the-Number Game)** Write an application that plays “guess the number” as follows: Your application chooses the number to be guessed by selecting an integer at random in the range 1–1000. The application then displays the following in a label:

I have a number between 1 and 1000. Can you guess my number?  
Please enter your first guess.

A `JTextField` should be used to input the guess. As each guess is input, the background color should change to either red or blue. Red indicates that the user is getting “warmer,” and blue, “colder.” A `JLabel` should display either “Too High” or “Too Low” to help the user zero in. When the user gets the correct answer, “Correct!” should be displayed, and the `JTextField` used for input should be changed to be uneditable. A `JButton` should be provided to allow the user to play the game again. When the `JButton` is clicked, a new random number should be generated and the input `JTextField` changed to be editable.

**14.15 (Displaying Events)** It’s often useful to display the events that occur during the execution of an application. This can help you understand when the events occur and how they’re generated. Write an application that enables the user to generate and process every event discussed in this chapter. The application should provide methods from the `ActionListener`, `ItemListener`, `ListSelectionListener`, `MouseListener`, `MouseMotionListener` and `KeyListener` interfaces to display messages when the events occur. Use method `toString` to convert the event objects received in each event handler into `Strings` that can be displayed. Method `toString` creates a `String` containing all the information in the event object.

**14.16 (GUI-Based Craps Game)** Modify the application of Section 6.10 to provide a GUI that enables the user to click a `JButton` to roll the dice. The application should also display four `JLabels` and four `JTextFields`, with one `JLabel` for each `JTextField`. The `JTextFields` should be used to display the values of each die and the sum of the dice after each roll. The point should be displayed in the fourth `JTextField` when the user does not win or lose on the first roll and should continue to be displayed until the game is lost.

### (Optional) GUI and Graphics Case Study Exercise: Expanding the Interface

**14.17 (Interactive Drawing Application)** In this exercise, you’ll implement a GUI application that uses the `MyShape` hierarchy from GUI and Graphics Case Study Exercise 10.2 to create an interactive drawing application. You’ll create two classes for the GUI and provide a test class that launches the application. The classes of the `MyShape` hierarchy require no additional changes.

The first class to create is a subclass of `JPanel` called `DrawPanel`, which represents the area on which the user draws the shapes. Class `DrawPanel` should have the following instance variables:

- An array `shapes` of type `MyShape` that will store all the shapes the user draws.
- An integer `shapeCount` that counts the number of shapes in the array.
- An integer `shapeType` that determines the type of shape to draw.
- A `MyShape` `currentShape` that represents the current shape the user is drawing.

- e) A `Color` `currentColor` that represents the current drawing color.
- f) A boolean `filledShape` that determines whether to draw a filled shape.
- g) A `JLabel` `statusLabel` that represents the status bar. The status bar will display the coordinates of the current mouse position.

Class `DrawPanel` should also declare the following methods:

- a) Overridden method `paintComponent` that draws the shapes in the array. Use instance variable `shapeCount` to determine how many shapes to draw. Method `paintComponent` should also call `currentShape`'s `draw` method, provided that `currentShape` is not `null`.
- b) Set methods for the `shapeType`, `currentColor` and `filledShape`.
- c) Method `clearLastShape` should clear the last shape drawn by decrementing instance variable `shapeCount`. Ensure that `shapeCount` is never less than zero.
- d) Method `clearDrawing` should remove all the shapes in the current drawing by setting `shapeCount` to zero.

Methods `clearLastShape` and `clearDrawing` should call `repaint` (inherited from `JPanel`) to refresh the drawing on the `DrawPanel` by indicating that the system should call method `paintComponent`.

Class `DrawPanel` should also provide event handling to enable the user to draw with the mouse. Create a single inner class that both extends `MouseAdapter` and implements `MouseListener` to handle all mouse events in one class.

In the inner class, override method `mousePressed` so that it assigns `currentShape` a new shape of the type specified by `shapeType` and initializes both points to the mouse position. Next, override method `mouseReleased` to finish drawing the current shape and place it in the array. Set the second point of `currentShape` to the current mouse position and add `currentShape` to the array. Instance variable `shapeCount` determines the insertion index. Set `currentShape` to `null` and call method `repaint` to update the drawing with the new shape.

Override method `mouseMoved` to set the text of the `statusLabel` so that it displays the mouse coordinates—this will update the label with the coordinates every time the user moves (but does not drag) the mouse within the `DrawPanel`. Next, override method `mouseDragged` so that it sets the second point of the `currentShape` to the current mouse position and calls method `repaint`. This will allow the user to see the shape while dragging the mouse. Also, update the `JLabel` in `mouseDragged` with the current position of the mouse.

Create a constructor for `DrawPanel` that has a single `JLabel` parameter. In the constructor, initialize `statusLabel` with the value passed to the parameter. Also initialize array `shapes` with 100 entries, `shapeCount` to 0, `shapeType` to the value that represents a line, `currentShape` to `null` and `currentColor` to `Color.BLACK`. The constructor should then set the background color of the `DrawPanel` to `Color.WHITE` and register the `MouseListener` and `MouseMotionListener` so the `JPanel` properly handles mouse events.

Next, create a `JFrame` subclass called `DrawFrame` that provides a GUI that enables the user to control various aspects of drawing. For the layout of the `DrawFrame`, we recommend a `BorderLayout`, with the components in the `NORTH` region, the main drawing panel in the `CENTER` region, and a status bar in the `SOUTH` region, as in Fig. 14.49. In the top panel, create the components listed below. Each component's event handler should call the appropriate method in class `DrawPanel`.

- a) A button to undo the last shape drawn.
- b) A button to clear all shapes from the drawing.
- c) A combo box for selecting the color from the 13 predefined colors.
- d) A combo box for selecting the shape to draw.
- e) A checkbox that specifies whether a shape should be filled or unfilled.

Declare and create the interface components in `DrawFrame`'s constructor. You'll need to create the status bar `JLabel` before you create the `DrawPanel`, so you can pass the `JLabel` as an argument to `DrawPanel`'s constructor. Finally, create a test class that initializes and displays the `DrawFrame` to execute the application.

**Fig. 14.49** | Interface for drawing shapes.

**14.18** (*GUI-Based Version of the ATM Case Study*) Reimplement the ATM Case Study of Chapters 12–13 as a GUI-based application. Use GUI components to approximate the ATM user interface shown in Fig. 12.1. For the cash dispenser and the deposit slot use `JButtons` labeled **Remove Cash** and **Insert Envelope**. This will enable the application to receive events indicating when the user takes the cash and inserts a deposit envelope, respectively.

## Making a Difference

**14.19** (*Ecofont*) Ecofont ([www.ecofont.eu/ecofont\\_en.html](http://www.ecofont.eu/ecofont_en.html))—developed by SPRANQ (a Netherlands-based company)—is a free, open-source computer font designed to reduce by as much as 20% the amount of ink used for printing, thus reducing also the number of ink cartridges used and the environmental impact of the manufacturing and shipping processes (using less energy, less fuel for shipping, and so on). The font, based on sans-serif Verdana, has small circular “holes” in the letters that are not visible in smaller sizes—such as the 9- or 10-point type frequently used. Download Ecofont, then install the font file `Spranq_eco_sans_regular.ttf` using the instructions from the Ecofont website. Next, develop a GUI-based program that allows you to type in a text string to be displayed in the Ecofont. Create **Increase Font Size** and **Decrease Font Size** buttons that allow you to scale up or down by one point at a time. Start with a default font size of 9 points. As you scale up, you’ll be able to see the holes in the letters more clearly. As you scale down, the holes will be less apparent. What is the smallest font size at which you begin to notice the holes?

**14.20** (*Typing Tutor: Tuning a Crucial Skill in the Computer Age*) Typing quickly and correctly is an essential skill for working effectively with computers and the Internet. In this exercise, you’ll build a GUI application that can help users learn to “touch type” (i.e., type correctly without looking at the keyboard). The application should display a *virtual keyboard* (Fig. 14.50) and should allow the user to watch what he or she is typing on the screen without looking at the *actual keyboard*. Use `JButtons` to represent the keys. As the user presses each key, the application highlights the corresponding `JButton` on the GUI and adds the character to a `JTextArea` that shows what the user has typed so far. [*Hint*: To highlight a `JButton`, use its `setBackground` method to change its background

color. When the key is released, reset its original background color. You can obtain the JButton's original background color with the `getBackground` method before you change its color.]

**Fig. 14.50** | Typing tutor.

You can test your program by typing a pangram—a phrase that contains every letter of the alphabet at least once—such as “The quick brown fox jumped over a lazy dog.” You can find other pangrams on the web.

To make the program more interesting you could monitor the user's accuracy. You could have the user type specific phrases that you've prestored in your program and that you display on the screen above the virtual keyboard. You could keep track of how many keystrokes the user types correctly and how many are typed incorrectly. You could also keep track of which keys the user is having difficulty with and display a report showing those keys.

*One picture is worth ten thousand words.*

—Chinese proverb

*Treat nature in terms of the cylinder, the sphere, the cone, all in perspective.*

—Paul Cézanne

*Colors, like features, follow the changes of the emotions.*

—Pablo Picasso

*Nothing ever becomes real till it is experienced—even a proverb is no proverb to you till your life has illustrated it.*

—John Keats

## Objectives

In this chapter you'll learn:

- To understand graphics contexts and graphics objects.
- To manipulate colors and fonts.
- To use methods of class `Graphics` to draw various shapes.
- To use methods of class `Graphics2D` from the Java 2D API to draw various shapes.
- To specify `Paint` and `Stroke` characteristics of shapes displayed with `Graphics2D`.

- |                                                    |                                            |

| <b>15.5</b> Drawing Lines, Rectangles and Ovals    |                                            |

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Optional GUI and Graphics Case Study: Adding Java 2D | Making a Difference*

## 15.1 Introduction

In this chapter, we overview several of Java’s capabilities for drawing two-dimensional shapes, controlling colors and controlling fonts. Part of Java’s initial appeal was its support for graphics that enabled programmers to visually enhance their applications. Java now contains many more sophisticated drawing capabilities as part of the Java 2D API. This chapter begins by introducing many of Java’s original drawing capabilities. Next we present several of the more powerful Java 2D capabilities, such as controlling the style of lines used to draw shapes and the way shapes are filled with colors and patterns. The classes that were part of Java’s original graphics capabilities are now considered to be part of the Java 2D API.

Figure 15.1 shows a portion of the Java class hierarchy that includes several of the basic graphics classes and Java 2D API classes and interfaces covered in this chapter. Class **Color** contains methods and constants for manipulating colors. Class **JComponent** contains method `paintComponent`, which is used to draw graphics on a component. Class **Font** contains methods and constants for manipulating fonts. Class **FontMetrics** contains methods for obtaining font information. Class **Graphics** contains methods for drawing strings, lines, rectangles and other shapes. Class **Graphics2D**, which extends class **Graphics**, is used for drawing with the Java 2D API. Class **Polygon** contains methods for creating polygons. The bottom half of the figure lists several classes and interfaces from the Java 2D API. Class **BasicStroke** helps specify the drawing characteristics of lines. Classes **GradientPaint** and **TexturePaint** help specify the characteristics for filling shapes with colors or patterns. Classes `GeneralPath`, `Line2D`, `Arc2D`, `Ellipse2D`, `Rectangle2D` and `RoundRectangle2D` represent several Java 2D shapes.

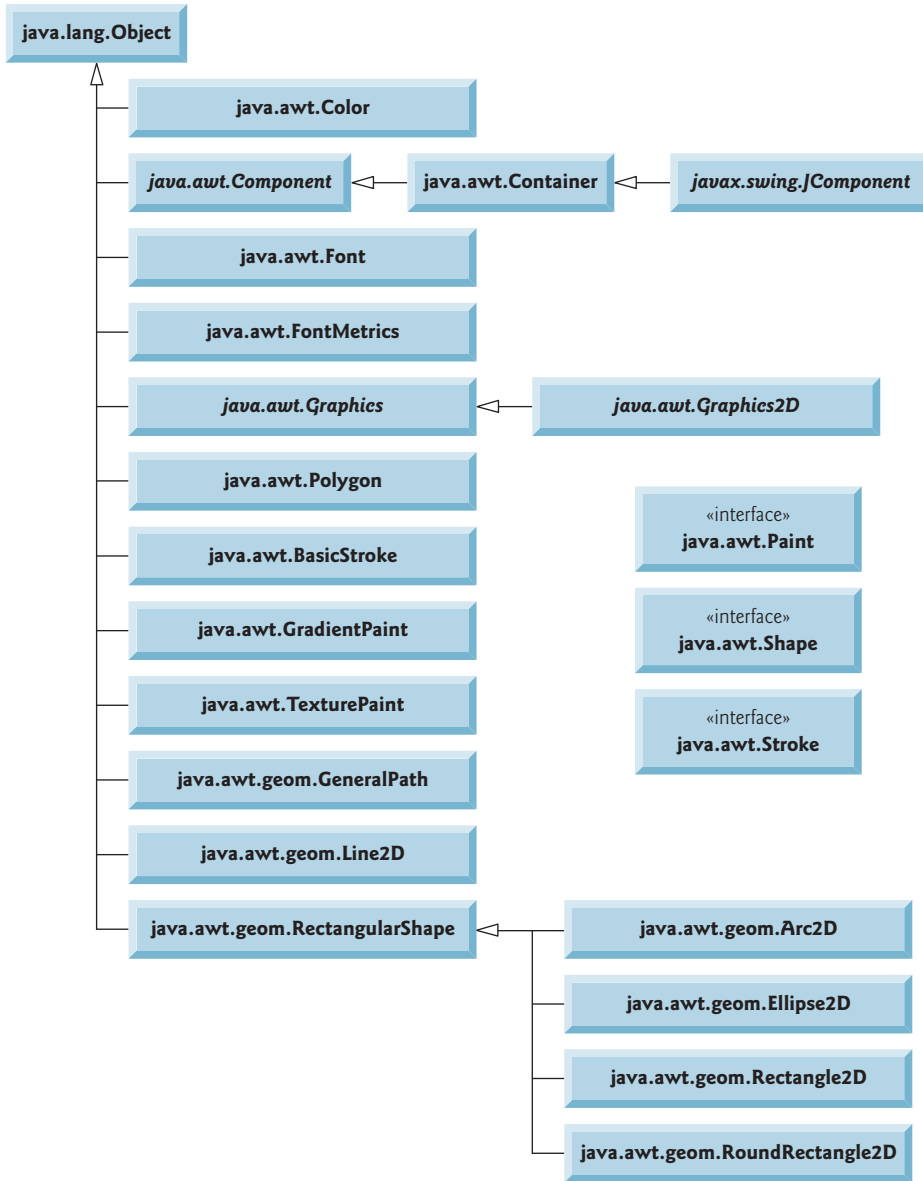

To begin drawing in Java, we must first understand Java’s **coordinate system** (Fig. 15.2), which is a scheme for identifying every point on the screen. By default, the upper-left corner of a GUI component (e.g., a window) has the coordinates (0, 0). A coordinate pair is composed of an **x-coordinate** (the **horizontal coordinate**) and a **y-coordinate** (the **vertical coordinate**). The **x-coordinate** is the horizontal distance moving *right* from the left of the screen. The **y-coordinate** is the vertical distance moving *down* from the top of the screen. The **x-axis** describes every horizontal coordinate, and the **y-axis** every vertical coordinate. The coordinates are used to indicate where graphics should be displayed on a screen. Coordinate units are measured in **pixels** (which stands for “picture element”). A pixel is a display monitor’s smallest unit of resolution.

**Portability Tip 15.1**

*Different display monitors have different resolutions (i.e., the density of the pixels varies). This can cause graphics to appear in different sizes on different monitors or on the same monitor with different settings.*

**Fig. 15.1** | Classes and interfaces used in this chapter from Java’s original graphics capabilities and from the Java 2D API.

**Fig. 15.2** | Java coordinate system. Units are measured in pixels.

## 15.2 Graphics Contexts and Graphics Objects

A **graphics context** enables drawing on the screen. A `Graphics` object manages a graphics context and draws pixels on the screen that represent text and other graphical objects (e.g., lines, ellipses, rectangles and other polygons). `Graphics` objects contain methods for drawing, font manipulation, color manipulation and the like.

Class `Graphics` is an abstract class (i.e., `Graphics` objects cannot be instantiated). This contributes to Java's portability. Because drawing is performed differently on every platform that supports Java, there cannot be only one implementation of the drawing capabilities across all systems. For example, the graphics capabilities that enable a PC running Microsoft Windows to draw a rectangle are different from those that enable a Linux workstation to draw a rectangle—and they're both different from the graphics capabilities that enable a Macintosh to draw a rectangle. When Java is implemented on each platform, a subclass of `Graphics` is created that implements the drawing capabilities. This implementation is hidden by class `Graphics`, which supplies the interface that enables us to use graphics in a platform-independent manner.

Recall from Chapter 14 that class `Component` is the superclass for many of the classes in package `java.awt`. Class `JComponent` (package `javax.swing`), which inherits indirectly from class `Component`, contains a `paintComponent` method that can be used to draw graphics. Method `paintComponent` takes a `Graphics` object as an argument. This object is passed to the `paintComponent` method by the system when a lightweight Swing component needs to be repainted. The header for the `paintComponent` method is

```
public void paintComponent( Graphics g )
```

Parameter `g` receives a reference to an instance of the system-specific subclass that `Graphics` extends. The preceding method header should look familiar to you—it's the same one we used in some of the applications in Chapter 14. Actually, class `JComponent` is a superclass of `JPanel`. Many capabilities of class `JPanel` are inherited from class `JComponent`.

You seldom call method `paintComponent` directly, because drawing graphics is an event-driven process. As we mentioned in Chapter 11, Java uses a multithreaded model of program execution. Each thread is a parallel activity. Each program can have many threads. When you create a GUI-based application, one of those threads is known as the **event-dispatch thread (EDT)**—it's used to process all GUI events. All drawing and manipulation of GUI components should be performed in that thread. When a GUI application executes, the application container calls method `paintComponent` (in the

event-dispatch thread) for each lightweight component as the GUI is displayed. For `paintComponent` to be called again, an event must occur (such as covering and uncovering the component with another window).

If you need `paintComponent` to execute (i.e., if you want to update the graphics drawn on a Swing component), you can call method **repaint**, which is inherited by all `JComponent`s indirectly from class `Component` (package `java.awt`). The header for `repaint` is

```
public void repaint()
```

## 15.3 Color Control

Class `Color` declares methods and constants for manipulating colors in a Java program. The predeclared color constants are summarized in Fig. 15.3, and several color methods and constructors are summarized in Fig. 15.4. Two of the methods in Fig. 15.4 are Graphics methods that are specific to colors.

| Color constant                                    | RGB value     |
|---------------------------------------------------|---------------|
| <code>public final static Color RED</code>        | 255, 0, 0     |
| <code>public final static Color GREEN</code>      | 0, 255, 0     |
| <code>public final static Color BLUE</code>       | 0, 0, 255     |
| <code>public final static Color ORANGE</code>     | 255, 200, 0   |
| <code>public final static Color PINK</code>       | 255, 175, 175 |
| <code>public final static Color CYAN</code>       | 0, 255, 255   |
| <code>public final static Color MAGENTA</code>    | 255, 0, 255   |
| <code>public final static Color YELLOW</code>     | 255, 255, 0   |
| <code>public final static Color BLACK</code>      | 0, 0, 0       |
| <code>public final static Color WHITE</code>      | 255, 255, 255 |
| <code>public final static Color GRAY</code>       | 128, 128, 128 |
| <code>public final static Color LIGHT_GRAY</code> | 192, 192, 192 |
| <code>public final static Color DARK_GRAY</code>  | 64, 64, 64    |

**Fig. 15.3** | `Color` constants and their RGB values.

| Method                                                 | Description                                                                                                 |
|--------------------------------------------------------|-------------------------------------------------------------------------------------------------------------|
| <i>Color constructors and methods</i>                  |                                                                                                             |
| <code>public Color( int r, int g, int b )</code>       | Creates a color based on red, green and blue components expressed as integers from 0 to 255.                |
| <code>public Color( float r, float g, float b )</code> | Creates a color based on red, green and blue components expressed as floating-point values from 0.0 to 1.0. |

**Fig. 15.4** | `Color` methods and color-related Graphics methods. (Part 1 of 2.)

| Method                                          | Description                                                                            |
|-------------------------------------------------|----------------------------------------------------------------------------------------|
| <code>public int getRed()</code>                | Returns a value between 0 and 255 representing the red content.                        |
| <code>public int getGreen()</code>              | Returns a value between 0 and 255 representing the green content.                      |
| <code>public int getBlue()</code>               | Returns a value between 0 and 255 representing the blue content.                       |
| <i>Graphics methods for manipulating Colors</i> |                                                                                        |
| <code>public Color getColor()</code>            | Returns <code>Color</code> object representing current color for the graphics context. |
| <code>public void setColor( Color c )</code>    | Sets the current color for drawing with the graphics context.                          |

**Fig. 15.4** | `Color` methods and color-related `Graphics` methods. (Part 2 of 2.)

Every color is created from a red, a green and a blue component. Together these components are called **RGB values**. All three RGB components can be integers in the range from 0 to 255, or all three can be floating-point values in the range 0.0 to 1.0. The first RGB component specifies the amount of red, the second the amount of green and the third the amount of blue. The larger the RGB value, the greater the amount of that particular color. Java enables you to choose from  $256 \times 256 \times 256$  (approximately 16.7 million) colors. Not all computers are capable of displaying all these colors. The computer will display the closest color it can.

Two of class `Color`'s constructors are shown in Fig. 15.4—one that takes three `int` arguments and one that takes three `float` arguments, with each argument specifying the amount of red, green and blue. The `int` values must be in the range 0–255 and the `float` values in the range 0.0–1.0. The new `Color` object will have the specified amounts of red, green and blue. `Color` methods **`getRed`**, **`getGreen`** and **`getBlue`** return integer values from 0 to 255 representing the amounts of red, green and blue, respectively. `Graphics` method **`getColor`** returns a `Color` object representing the current drawing color. `Graphics` method **`setColor`** sets the current drawing color.

### *Drawing in Different Colors*

Figures 15.5–15.6 demonstrate several methods from Fig. 15.4 by drawing filled rectangles and `Strings` in several different colors. When the application begins execution, class `ColorJPanel`'s `paintComponent` method (lines 10–37 of Fig. 15.5) is called to paint the window. Line 17 uses `Graphics` method `setColor` to set the drawing color. Method `setColor` receives a `Color` object. The expression `new Color( 255, 0, 0 )` creates a new `Color` object that represents red (red value 255, and 0 for the green and blue values). Line 18 uses `Graphics` method **`fillRect`** to draw a filled rectangle in the current color. Method `fillRect` draws a rectangle based on its four arguments. The first two integer values represent the upper-left *x*-coordinate and upper-left *y*-coordinate, where the `Graphics` object begins drawing the rectangle. The third and fourth arguments are nonnegative integers that

represent the width and the height of the rectangle in pixels, respectively. A rectangle drawn using method `fillRect` is filled by the current color of the `Graphics` object.

6
7 public class ColorJPanel extends JPanel
8 {
9     // draw rectangles and Strings in different colors
10    public void paintComponent( Graphics g )
11    {
12        super.paintComponent( g ); // call superclass's paintComponent
13
14        this.setBackground( Color.WHITE );
15
16        // set new drawing color using integers
17        g.setColor( new Color( 255, 0, 0 ) );
18        g.fillRect( 15, 25, 100, 20 );
19        g.drawString( "Current RGB: " + g.getColor(), 130, 40 );
20
21        // set new drawing color using floats
22        g.setColor( new Color( 0.50f, 0.75f, 0.0f ) );
23        g.fillRect( 15, 50, 100, 20 );
24        g.drawString( "Current RGB: " + g.getColor(), 130, 65 );
25
26        // set new drawing color using static Color objects
27        g.setColor( Color.BLUE );
28        g.fillRect( 15, 75, 100, 20 );
29        g.drawString( "Current RGB: " + g.getColor(), 130, 90 );
30
31        // display individual RGB values
32        Color color = Color.MAGENTA;
33        g.setColor( color );
34        g.fillRect( 15, 100, 100, 20 );
35        g.drawString( "RGB values: " + color.getRed() + ", " +
36                    color.getGreen() + ", " + color.getBlue(), 130, 115 );
37    } // end method paintComponent
38 } // end class ColorJPanel

```

---

**Fig. 15.5** | Color changed for drawing.

---

```

1 // Fig. 15.6: ShowColors.java
2 // Demonstrating Colors.
3 import javax.swing.JFrame;
4
5 public class ShowColors
6 {

```

---

**Fig. 15.6** | Creating `JFrame` to display colors on `JPanel`. (Part I of 2.)

```

7 // execute application
8 public static void main( String[] args )
9 {
10 // create frame for ColorJPanel
11 JFrame frame = new JFrame( "Using colors" );
12 frame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
13
14 ColorJPanel colorJPanel = new ColorJPanel(); // create ColorJPanel
15 frame.add( colorJPanel ); // add colorJPanel to frame
16 frame.setSize( 400, 180 ); // set frame size
17 frame.setVisible( true ); // display frame
18 } // end main
19 } // end class ShowColors

```

**Fig. 15.6** | Creating JFrame to display colors on JPanel. (Part 2 of 2.)

Line 19 (Fig. 15.5) uses Graphics method **drawString** to draw a String in the current color. The expression `g.getColor()` retrieves the current color from the Graphics object. We then concatenate the Color with string "Current RGB: ", resulting in an implicit call to class Color's `toString` method. The String representation of a Color contains the class name and package (`java.awt.Color`) and the red, green and blue values.

### Look-and-Feel Observation 15.1

*People perceive colors differently. Choose your colors carefully to ensure that your application is readable, both for people who can perceive color and for those who are color blind. Try to avoid using many different colors in close proximity.*

Lines 22–24 and 27–29 perform the same tasks again. Line 22 uses the Color constructor with three float arguments to create a dark green color (0.50f for red, 0.75f for green and 0.0f for blue). Note the syntax of the values. The letter f appended to a floating-point literal indicates that the literal should be treated as type float. Recall that by default, floating-point literals are treated as type double.

Line 27 sets the current drawing color to one of the predeclared Color constants (Color.BLUE). The Color constants are static, so they're created when class Color is loaded into memory at execution time.

The statement in lines 35–36 makes calls to Color methods `getRed`, `getGreen` and `getBlue` on the predeclared Color.MAGENTA constant. Method `main` of class ShowColors (lines 8–18 of Fig. 15.6) creates the JFrame that will contain a ColorJPanel object where the colors will be displayed.

### Software Engineering Observation 15.1

To change the color, you must create a new `Color` object (or use one of the predeclared `Color` constants). Like `String` objects, `Color` objects are immutable (not modifiable).

Package `javax.swing` provides the `JColorChooser` GUI component that enables application users to select colors. The application of Figs. 15.7–15.8 demonstrates a `JColorChooser` dialog. When you click the **Change Color** button, a `JColorChooser` dialog appears. When you select a color and press the dialog's **OK** button, the background color of the application window changes.

```

1 // Fig. 15.7: ShowColors2JFrame.java

8 import javax.swing.JFrame;
9 import javax.swing.JColorChooser;
10 import javax.swing.JPanel;
11
12 public class ShowColors2JFrame extends JFrame
13 {
14     private JButton changeColorJButton;
15     private Color color = Color.LIGHT_GRAY;
16     private JPanel colorJPanel;
17
18     // set up GUI
19     public ShowColors2JFrame()
20     {
21         super( "Using JColorChooser" );
22
23         // create JPanel for display color
24         colorJPanel = new JPanel();
25         colorJPanel.setBackground( color );
26
27         // set up changeColorJButton and register its event handler
28         changeColorJButton = new JButton( "Change Color" );
29         changeColorJButton.addActionListener(
30
31             new ActionListener() // anonymous inner class
32             {
33                 // display JColorChooser when user clicks button
34                 public void actionPerformed( ActionEvent event )
35                 {
36                     color = JColorChooser.showDialog(
37                         ShowColors2JFrame.this, "Choose a color", color );
38
39                     // set default color, if no color is returned
40                     if ( color == null )
41                         color = Color.LIGHT_GRAY;

```

**Fig. 15.7** | `JColorChooser` dialog. (Part I of 2.)

```

42
43         // change content pane's background color
44         colorJPanel.setBackground( color );
45     } // end method actionPerformed
46 } // end anonymous inner class
47 ); // end call to addActionListener
48
49 add( colorJPanel, BorderLayout.CENTER ); // add colorJPanel
50 add( changeColorJButton, BorderLayout.SOUTH ); // add button

one of the color  
swatches

(c) Application window after changing JPanel's  
background color

**Fig. 15.8** | Choosing colors with JColorChooser.

Class `JColorChooser` provides static method `showDialog`, which creates a `JColorChooser` object, attaches it to a dialog box and displays the dialog. Lines 36–37 of Fig. 15.7 invoke this method to display the color chooser dialog. Method `showDialog` returns the selected `Color` object, or `null` if the user presses **Cancel** or closes the dialog without pressing **OK**. The method takes three arguments—a reference to its parent `Component`, a `String` to display in the title bar of the dialog and the initial selected `Color` for the dialog. The parent component is a reference to the window from which the dialog is displayed (in this case the `JFrame`, with the reference name `frame`). The dialog will be centered on the parent. If the parent is `null`, the dialog is centered on the screen. While the color chooser dialog is on the screen, the user cannot interact with the parent component until the dialog is dismissed. This type of dialog is called a modal dialog.

After the user selects a color, lines 40–41 determine whether `color` is `null`, and, if so, set `color` to `Color.LIGHT_GRAY`. Line 44 invokes method `setBackground` to change the background color of the `JPanel`. Method `setBackground` is one of the many `Component` methods that can be used on most GUI components. The user can continue to use the **Change Color** button to change the background color of the application. Figure 15.8 contains method `main`, which executes the program.

Figure 15.8(b) shows the default `JColorChooser` dialog that allows the user to select a color from a variety of **color swatches**. There are three tabs across the top of the dialog—**Swatches**, **HSB** and **RGB**. These represent three different ways to select a color. The **HSB** tab allows you to select a color based on **hue**, **saturation** and **brightness**—values that are used to define the amount of light in a color. We do not discuss HSB values. For more information on them, visit [en.wikipedia.org/wiki/HSL\\_and\\_HSV](http://en.wikipedia.org/wiki/HSL_and_HSV). The **RGB** tab allows you to select a color by using sliders to select the red, green and blue components. The **HSB** and **RGB** tabs are shown in Fig. 15.9.

**Fig. 15.9** | HSB and RGB tabs of the `JColorChooser` dialog. (Part 1 of 2.)

**Fig. 15.9** | HSB and RGB tabs of the `JColorChooser` dialog. (Part 2 of 2.)

## 15.4 Manipulating Fonts

This section introduces methods and constants for manipulating fonts. Most font methods and font constants are part of class `Font`. Some methods of class `Font` and class `Graphics` are summarized in Fig. 15.10.

| Method or constant                                               | Description                                                                      |
|------------------------------------------------------------------|----------------------------------------------------------------------------------|
| <i>Font constants, constructors and methods</i>                  |                                                                                  |
| <code>public final static int PLAIN</code>                       | A constant representing a plain font style.                                      |
| <code>public final static int BOLD</code>                        | A constant representing a bold font style.                                       |
| <code>public final static int ITALIC</code>                      | A constant representing an italic font style.                                    |
| <code>public Font( String name,<br/>int style, int size )</code> | Creates a <code>Font</code> object with the specified font name, style and size. |
| <code>public int getStyle()</code>                               | Returns an <code>int</code> indicating the current font style.                   |
| <code>public int getSize()</code>                                | Returns an <code>int</code> indicating the current font size.                    |
| <code>public String getName()</code>                             | Returns the current font name as a string.                                       |
| <code>public String getFamily()</code>                           | Returns the font's family name as a string.                                      |
| <code>public boolean isPlain()</code>                            | Returns <code>true</code> if the font is plain, else <code>false</code> .        |
| <code>public boolean isBold()</code>                             | Returns <code>true</code> if the font is bold, else <code>false</code> .         |
| <code>public boolean isItalic()</code>                           | Returns <code>true</code> if the font is italic, else <code>false</code> .       |

**Fig. 15.10** | Font-related methods and constants. (Part 1 of 2.)

| Method or constant                             | Description                                                                                                            |
|------------------------------------------------|------------------------------------------------------------------------------------------------------------------------|
| <i>Graphics methods for manipulating Fonts</i> |                                                                                                                        |
| <code>public Font getFont()</code>             | Returns a <code>Font</code> object reference representing the current font.                                            |
| <code>public void setFont( Font f )</code>     | Sets the current font to the font, style and size specified by the <code>Font</code> object reference <code>f</code> . |

**Fig. 15.10** | Font-related methods and constants. (Part 2 of 2.)

Class `Font`'s constructor takes three arguments—the **font name**, **font style** and **font size**. The font name is any font currently supported by the system on which the program is running, such as standard Java fonts `Monospaced`, `SansSerif` and `Serif`. The font style is **`Font.PLAIN`**, **`Font.ITALIC`** or **`Font.BOLD`** (each is a static field of class `Font`). Font styles can be used in combination (e.g., `Font.ITALIC + Font.BOLD`). The font size is measured in points. A **point** is 1/72 of an inch. `Graphics` method **`setFont`** sets the current drawing font—the font in which text will be displayed—to its `Font` argument.

### Portability Tip 15.2

*The number of fonts varies across systems. Java provides five font names—`Serif`, `Monospaced`, `SansSerif`, `Dialog` and `DialogInput`—that can be used on all Java platforms. The Java runtime environment (JRE) on each platform maps these logical font names to actual fonts installed on the platform. The actual fonts used may vary by platform.*

The application of Figs. 15.11–15.12 displays text in four different fonts, with each font in a different size. Figure 15.11 uses the `Font` constructor to initialize `Font` objects (in lines 16, 20, 24 and 29) that are each passed to `Graphics` method `setFont` to change the drawing font. Each call to the `Font` constructor passes a font name (`Serif`, `Monospaced` or `SansSerif`) as a string, a font style (`Font.PLAIN`, `Font.ITALIC` or `Font.BOLD`) and a font size. Once `Graphics` method `setFont` is invoked, all text displayed following the call will appear in the new font until the font is changed. Each font's information is displayed in lines 17, 21, 25 and 30–31 using method `drawString`. The coordinates passed to `drawString` corresponds to the lower-left corner of the baseline of the font. Line 28 changes the drawing color to red, so the next string displayed appears in red. Lines 30–31 display information about the final `Font` object. Method **`getFont`** of class `Graphics` returns a `Font` object representing the current font. Method **`getName`** returns the current font name as a string. Method **`getSize`** returns the font size in points.

### Software Engineering Observation 15.2

*To change the font, you must create a new `Font` object. `Font` objects are immutable—class `Font` has no set methods to change the characteristics of the current font.*

Figure 15.12 contains the main method, which creates a `JFrame` to display a `FontJPanel`. We add a `FontJPanel` object to this `JFrame` (line 15), which displays the graphics created in Fig. 15.11.

```

**Fig. 15.12** | Creating a JFrame to display fonts. (Part 2 of 2.)

### Font Metrics

Sometimes it's necessary to get information about the current drawing font, such as its name, style and size. Several `Font` methods used to get font information are summarized in Fig. 15.10. Method `getStyle` returns an integer value representing the current style. The integer value returned is either `Font.PLAIN`, `Font.ITALIC`, `Font.BOLD` or the combination of `Font.ITALIC` and `Font.BOLD`. Method `getFamily` returns the name of the font family to which the current font belongs. The name of the font family is platform specific. `Font` methods are also available to test the style of the current font, and these too are summarized in Fig. 15.10. Methods `isPlain`, `isBold` and `isItalic` return `true` if the current font style is plain, bold or italic, respectively.

Figure 15.13 illustrates some of the common **font metrics**, which provide precise information about a font, such as **height**, **descent** (the amount a character dips below the baseline), **ascent** (the amount a character rises above the baseline) and **leading** (the difference between the descent of one line of text and the ascent of the line of text below it—that is, the interline spacing).

**Fig. 15.13** | Font metrics.

Class `FontMetrics` declares several methods for obtaining font metrics. These methods and `Graphics` method `getFontMetrics` are summarized in Fig. 15.14. The application of Figs. 15.15–15.16 uses the methods of Fig. 15.14 to obtain font metric information for two fonts.

| Method                                                   | Description                                                     |
|----------------------------------------------------------|-----------------------------------------------------------------|
| <i>FontMetrics methods</i>                               |                                                                 |
| <code>public int getAscent()</code>                      | Returns the ascent of a font in points.                         |
| <code>public int getDescent()</code>                     | Returns the descent of a font in points.                        |
| <code>public int getLeading()</code>                     | Returns the leading of a font in points.                        |
| <code>public int getHeight()</code>                      | Returns the height of a font in points.                         |
| <i>Graphics methods for getting a Font's FontMetrics</i> |                                                                 |
| <code>public FontMetrics getFontMetrics()</code>         | Returns the FontMetrics object for the current drawing Font.    |
| <code>public FontMetrics getFontMetrics( Font f )</code> | Returns the FontMetrics object for the specified Font argument. |

18     } // end main
19 } // end class Metrics

```

**Fig. 15.16** | Creating JFrame to display font metric information.

Line 15 of Fig. 15.15 creates and sets the current drawing font to a SansSerif, bold, 12-point font. Line 16 uses Graphics method `getFontMetrics` to obtain the `FontMetrics` object for the current font. Line 17 outputs the `String` representation of the `Font` returned by `g.getFont()`. Lines 18–21 use `FontMetric` methods to obtain the ascent, descent, height and leading for the font.

Line 23 creates a new `Serif`, italic, 14-point font. Line 24 uses a second version of Graphics method `getFontMetrics`, which accepts a `Font` argument and returns a corresponding `FontMetrics` object. Lines 27–30 obtain the ascent, descent, height and leading for the font. The font metrics are slightly different for the two fonts.

## 15.5 Drawing Lines, Rectangles and Ovals

This section presents Graphics methods for drawing lines, rectangles and ovals. The methods and their parameters are summarized in Fig. 15.17. For each drawing method that requires a width and height parameter, the width and height must be nonnegative values. Otherwise, the shape will not display.

| Method                                                                                                     | Description                                                                                                                                                                                                                                                                           |
|------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>public void drawLine( int x1, int y1, int x2, int y2 )</code>                                        | Draws a line between the point (x1, y1) and the point (x2, y2).                                                                                                                                                                                                                       |
| <code>public void drawRect( int x, int y, int width, int height )</code>                                   | Draws a rectangle of the specified width and height. The rectangle's top-left corner is located at (x, y). Only the outline of the rectangle is drawn using the Graphics object's color—the body of the rectangle is not filled with this color.                                      |
| <code>public void fillRect( int x, int y, int width, int height )</code>                                   | Draws a filled rectangle in the current color with the specified width and height. The rectangle's top-left corner is located at (x, y).                                                                                                                                              |
| <code>public void clearRect( int x, int y, int width, int height )</code>                                  | Draws a filled rectangle with the specified width and height in the current background color. The rectangle's top-left corner is located at (x, y). This method is useful if you want to remove a portion of an image.                                                                |
| <code>public void drawRoundRect( int x, int y, int width, int height, int arcWidth, int arcHeight )</code> | Draws a rectangle with rounded corners in the current color with the specified width and height. The arcWidth and arcHeight determine the rounding of the corners (see Fig. 15.20). Only the outline of the shape is drawn.                                                           |
| <code>public void fillRoundRect( int x, int y, int width, int height, int arcWidth, int arcHeight )</code> | Draws a filled rectangle in the current color with rounded corners with the specified width and height. The arcWidth and arcHeight determine the rounding of the corners (see Fig. 15.20).                                                                                            |
| <code>public void draw3DRect( int x, int y, int width, int height, boolean b )</code>                      | Draws a three-dimensional rectangle in the current color with the specified width and height. The rectangle's top-left corner is located at (x, y). The rectangle appears raised when b is true and lowered when b is false. Only the outline of the shape is drawn.                  |
| <code>public void fill3DRect( int x, int y, int width, int height, boolean b )</code>                      | Draws a filled three-dimensional rectangle in the current color with the specified width and height. The rectangle's top-left corner is located at (x, y). The rectangle appears raised when b is true and lowered when b is false.                                                   |
| <code>public void drawOval( int x, int y, int width, int height )</code>                                   | Draws an oval in the current color with the specified width and height. The bounding rectangle's top-left corner is located at (x, y). The oval touches all four sides of the bounding rectangle at the center of each side (see Fig. 15.21). Only the outline of the shape is drawn. |
| <code>public void fillOval( int x, int y, int width, int height )</code>                                   | Draws a filled oval in the current color with the specified width and height. The bounding rectangle's top-left corner is located at (x, y). The oval touches the center of all four sides of the bounding rectangle (see Fig. 15.21).                                                |

**Fig. 15.17** | Graphics methods that draw lines, rectangles and ovals.

The application of Figs. 15.18–15.19 demonstrates drawing a variety of lines, rectangles, three-dimensional rectangles, rounded rectangles and ovals. In Fig. 15.18, line 17 draws a red line, line 20 draws an empty blue rectangle and line 21 draws a filled blue rectangle. Methods `fillRoundRect` (line 24) and `drawRoundRect` (line 25) draw rectangles with rounded corners. Their first two arguments specify the coordinates of the upper-left corner of the **bounding rectangle**—the area in which the rounded rectangle will be drawn. The upper-left corner coordinates are *not* the edge of the rounded rectangle, but the coordinates where the edge would be if the rectangle had square corners. The third and fourth arguments specify the width and height of the rectangle. The last two arguments determine the horizontal and vertical diameters of the arc (i.e., the arc width and arc height) used to represent the corners.

Figure 15.20 labels the arc width, arc height, width and height of a rounded rectangle. Using the same value for the arc width and arc height produces a quarter-circle at each

```

**Fig. 15.19** | Creating JFrame to display lines, rectangles and ovals.

**Fig. 15.20** | Arc width and arc height for rounded rectangles.

corner. When the arc width, arc height, width and height have the same values, the result is a circle. If the values for width and height are the same and the values of arcWidth and arcHeight are 0, the result is a square.

Methods `draw3DRect` (line 28) and `fill3DRect` (line 29) take the same arguments. The first two specify the top-left corner of the rectangle. The next two arguments specify the width and height of the rectangle, respectively. The last argument determines whether the rectangle is **raised** (true) or **lowered** (false). The three-dimensional effect of `draw3DRect` appears as two edges of the rectangle in the original color and two edges in a slightly darker color. The three-dimensional effect of `fill3DRect` appears as two edges of the rectangle in the original drawing color and the fill and other two edges in a slightly darker color. Raised rectangles have the original drawing color edges at the top and left of the rectangle. Lowered rectangles have the original drawing color edges at the bottom and right of the rectangle. The three-dimensional effect is difficult to see in some colors.

Methods `drawOval` and `fillOval` (Fig. 15.18, lines 32–33) take the same four arguments. The first two specify the top-left coordinate of the bounding rectangle that contains the oval. The last two specify the width and height of the bounding rectangle, respectively. Figure 15.21 shows an oval bounded by a rectangle. The oval touches the center of all four sides of the bounding rectangle. (The bounding rectangle is not displayed on the screen.)

**Fig. 15.21** | Oval bounded by a rectangle.

## 15.6 Drawing Arcs

An **arc** is drawn as a portion of an oval. Arc angles are measured in degrees. Arcs **sweep** (i.e., move along a curve) from a **starting angle** through the number of degrees specified by their **arc angle**. The starting angle indicates in degrees where the arc begins. The arc angle specifies the total number of degrees through which the arc sweeps. Figure 15.22 illustrates two arcs. The left set of axes shows an arc sweeping from zero degrees to approximately 110 degrees. Arcs that sweep in a counterclockwise direction are measured in **positive degrees**. The set of axes on the right shows an arc sweeping from zero degrees to approximately  $-110$  degrees. Arcs that sweep in a clockwise direction are measured in **negative degrees**. Note the dashed boxes around the arcs in Fig. 15.22. When drawing an arc, we specify a bounding rectangle for an oval. The arc will sweep along part of the oval. Graphics methods `drawArc` and `fillArc` for drawing arcs are summarized in Fig. 15.23.

**Fig. 15.22** | Positive and negative arc angles.

| Method                                                                                              | Description                                                                                                                                                                                                                                               |
|-----------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <pre>public void drawArc( int x, int y, int width, int height, int startAngle, int arcAngle )</pre> | <p>Draws an arc relative to the bounding rectangle's top-left x- and y-coordinates with the specified width and height. The arc segment is drawn starting at <code>startAngle</code> and sweeps <code>arcAngle</code> degrees.</p>                        |
| <pre>public void fillArc( int x, int y, int width, int height, int startAngle, int arcAngle )</pre> | <p>Draws a filled arc (i.e., a sector) relative to the bounding rectangle's top-left x- and y-coordinates with the specified width and height. The arc segment is drawn starting at <code>startAngle</code> and sweeps <code>arcAngle</code> degrees.</p> |

**Fig. 15.23** | Graphics methods for drawing arcs.

Figures 15.24–15.25 demonstrate the arc methods of Fig. 15.23. The application draws six arcs (three unfilled and three filled). To illustrate the bounding rectangle that helps determine where the arc appears, the first three arcs are displayed inside a red rectangle that has the same x, y, width and height arguments as the arcs.

## 15.7 Drawing Polygons and Polylines

**Polygons** are closed multisided shapes composed of straight-line segments. **Polylines** are sequences of connected points. Figure 15.26 discusses methods for drawing polygons and polylines. Some methods require a **Polygon** object (package `java.awt`). Class `Polygon`'s constructors are also described in Fig. 15.26. The application of Figs. 15.27–15.28 draws polygons and polylines.

| Method                                                                            | Description                                                                                                                                                                                                                                                                                                                                                                                                 |
|-----------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>Graphics methods for drawing polygons</i>                                      |                                                                                                                                                                                                                                                                                                                                                                                                             |
| <code>public void drawPolygon( int[] xPoints, int[] yPoints, int points )</code>  | Draws a polygon. The <i>x</i> -coordinate of each point is specified in the <code>xPoints</code> array and the <i>y</i> -coordinate of each point in the <code>yPoints</code> array. The last argument specifies the number of points. This method draws a closed polygon. If the last point is different from the first, the polygon is closed by a line that connects the last point to the first.        |
| <code>public void drawPolyline( int[] xPoints, int[] yPoints, int points )</code> | Draws a sequence of connected lines. The <i>x</i> -coordinate of each point is specified in the <code>xPoints</code> array and the <i>y</i> -coordinate of each point in the <code>yPoints</code> array. The last argument specifies the number of points. If the last point is different from the first, the polyline is not closed.                                                                       |
| <code>public void drawPolygon( Polygon p )</code>                                 | Draws the specified polygon.                                                                                                                                                                                                                                                                                                                                                                                |
| <code>public void fillPolygon( int[] xPoints, int[] yPoints, int points )</code>  | Draws a filled polygon. The <i>x</i> -coordinate of each point is specified in the <code>xPoints</code> array and the <i>y</i> -coordinate of each point in the <code>yPoints</code> array. The last argument specifies the number of points. This method draws a closed polygon. If the last point is different from the first, the polygon is closed by a line that connects the last point to the first. |
| <code>public void fillPolygon( Polygon p )</code>                                 | Draws the specified filled polygon. The polygon is closed.                                                                                                                                                                                                                                                                                                                                                  |

**Fig. 15.26** | Graphics methods for polygons and class `Polygon` methods. (Part 1 of 2.)

| Method                                                                          | Description                                                                                                                                                                        |
|---------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>Polygon constructors and methods</i>                                         |                                                                                                                                                                                    |
| <code>public Polygon()</code>                                                   | Constructs a new polygon object. The polygon does not contain any points.                                                                                                          |
| <code>public Polygon( int[] xValues, int[] yValues, int numberOfPoints )</code> | Constructs a new polygon object. The polygon has numberOfPoints sides, with each point consisting of an <i>x</i> -coordinate from xValues and a <i>y</i> -coordinate from yValues. |
| <code>public void addPoint( int x, int y )</code>                               | Adds pairs of <i>x</i> - and <i>y</i> -coordinates to the Polygon.                                                                                                                 |

13
14        PolygonsJPanel polygonsJPanel = new PolygonsJPanel();
15        frame.add( polygonsJPanel ); // add polygonsJPanel to frame
16        frame.setSize( 280, 270 ); // set frame size
17        frame.setVisible( true ); // display frame
18    } // end main
19 } // end class DrawPolygons

```

**Fig. 15.28** | Creating `JFrame` to display polygons.

Lines 15–16 of Fig. 15.27 create two `int` arrays and use them to specify the points for Polygon `polygon1`. The `Polygon` constructor call in line 17 receives array `xValues`, which contains the  $x$ -coordinate of each point; array `yValues`, which contains the  $y$ -coordinate of each point; and 6 (the number of points in the polygon). Line 18 displays `polygon1` by passing it as an argument to `Graphics` method `drawPolygon`.

Lines 21–22 create two `int` arrays and use them to specify the points for a series of connected lines. Array `xValues2` contains the  $x$ -coordinate of each point and array `yValues2` the  $y$ -coordinate of each point. Line 23 uses `Graphics` method `drawPolyline` to

display the series of connected lines specified with the arguments `xValues2`, `yValues2` and 7 (the number of points).

Lines 26–27 create two `int` arrays and use them to specify the points of a polygon. Array `xValues3` contains the *x*-coordinate of each point and array `yValues3` the *y*-coordinate of each point. Line 28 displays a polygon by passing to Graphics method **fillPolygon** the two arrays (`xValues3` and `yValues3`) and the number of points to draw (4).

### Common Programming Error 15.1

*An `ArrayIndexOutOfBoundsException` is thrown if the number of points specified in the third argument to method `drawPolygon` or method `fillPolygon` is greater than the number of elements in the arrays of coordinates that specify the polygon to display.*

Line 31 creates Polygon `polygon2` with no points. Lines 32–36 use Polygon method **addPoint** to add pairs of *x*- and *y*-coordinates to the Polygon. Line 37 displays Polygon `polygon2` by passing it to Graphics method `fillPolygon`.

## 15.8 Java 2D API

The **Java 2D API** provides advanced two-dimensional graphics capabilities for programmers who require detailed and complex graphical manipulations. The API includes features for processing line art, text and images in packages `java.awt`, `java.awt.image`, `java.awt.color`, `java.awt.font`, `java.awt.geom`, `java.awt.print` and `java.awt.image.renderable`. The capabilities of the API are far too broad to cover in this textbook. For an overview, see the Java 2D demo (discussed in Chapter 23, Applets and Java Web Start) or visit [download.oracle.com/javase/6/docs/technotes/guides/2d/](http://download.oracle.com/javase/6/docs/technotes/guides/2d/). In this section, we overview several Java 2D capabilities.

Drawing with the Java 2D API is accomplished with a **Graphics2D** reference (package `java.awt`). `Graphics2D` is an abstract subclass of class `Graphics`, so it has all the graphics capabilities demonstrated earlier in this chapter. In fact, the actual object used to draw in every `paintComponent` method is an instance of a subclass of `Graphics2D` that is passed to method `paintComponent` and accessed via the superclass `Graphics`. To access `Graphics2D` capabilities, we must cast the `Graphics` reference (`g`) passed to `paintComponent` into a `Graphics2D` reference with a statement such as

```
Graphics2D g2d = ( Graphics2D ) g;
```

The next two examples use this technique.

### *Lines, Rectangles, Round Rectangles, Arcs and Ellipses*

This example demonstrates several Java 2D shapes from package `java.awt.geom`, including **Line2D.Double**, **Rectangle2D.Double**, **RoundRectangle2D.Double**, **Arc2D.Double** and **Ellipse2D.Double**. Note the syntax of each class name. Each class represents a shape with dimensions specified as `double` values. There's a separate version of each represented with `float` values (e.g., **Ellipse2D.Float**). In each case, `Double` is a `public static` nested class of the class specified to the left of the dot (e.g., `Ellipse2D`). To use the `static` nested class, we simply qualify its name with the outer class name.

In Figs. 15.29–15.30, we draw Java 2D shapes and modify their drawing characteristics, such as changing line thickness, filling shapes with patterns and drawing dashed lines. These are just a few of the many capabilities provided by Java 2D.

Line 25 of Fig. 15.29 casts the Graphics reference received by paintComponent to a Graphics2D reference and assigns it to g2d to allow access to the Java 2D features.

### *Ovals, Gradient Fills and Paint Objects*

The first shape we draw is an oval filled with gradually changing colors. Lines 28–29 invoke Graphics2D method **setPaint** to set the **Paint** object that determines the color for the shape to display. A **Paint** object implements interface `java.awt.Paint`. It can be something as simple as one of the predeclared `Color` objects introduced in Section 15.3 (class `Color` implements `Paint`), or it can be an instance of the Java 2D API's `GradientPaint`, `SystemColor`, `TexturePaint`, `LinearGradientPaint` or `RadialGradientPaint` classes. In this case, we use a `GradientPaint` object.

Class `GradientPaint` helps draw a shape in gradually changing colors—called a **gradient**. The `GradientPaint` constructor used here requires seven arguments. The first two specify the starting coordinate for the gradient. The third specifies the starting `Color` for the gradient. The fourth and fifth specify the ending coordinate for the gradient. The sixth specifies the ending `Color` for the gradient. The last argument specifies whether the gradient is **cyclic** (`true`) or **acyclic** (`false`). The two sets of coordinates determine the direction of the gradient. Because the second coordinate (35, 100) is down and to the right of the first coordinate (5, 30), the gradient goes down and to the right at an angle. Because this gradient is cyclic (`true`), the color starts with blue, gradually becomes yellow, then gradually returns to blue. If the gradient is acyclic, the color transitions from the first color specified (e.g., blue) to the second color (e.g., yellow).

Line 30 uses Graphics2D method **fill** to draw a filled **Shape** object—an object that implements interface `Shape` (package `java.awt`). In this case, we display an `Ellipse2D.Double` object. The `Ellipse2D.Double` constructor receives four arguments specifying the bounding rectangle for the ellipse to display.

### *Rectangles, Strokes*

Next we draw a red rectangle with a thick border. Line 33 invokes `setPaint` to set the `Paint` object to `Color.RED`. Line 34 uses Graphics2D method **setStroke** to set the characteristics of the rectangle's border (or the lines for any other shape). Method `setStroke` requires as its argument an object that implements interface **Stroke** (package `java.awt`). In this case, we use an instance of class `BasicStroke`. Class `BasicStroke` provides several constructors to specify the width of the line, how the line ends (called the **end caps**), how lines join together (called **line joins**) and the dash attributes of the line (if it's a dashed line). The constructor here specifies that the line should be 10 pixels wide.

Line 35 uses Graphics2D method **draw** to draw a `Shape` object—in this case, a `Rectangle2D.Double`. The `Rectangle2D.Double` constructor receives arguments specifying the rectangle's upper-left *x*-coordinate, upper-left *y*-coordinate, width and height.

### *Rounded Rectangles, BufferedImages and TexturePaint Objects*

Next we draw a rounded rectangle filled with a pattern created in a **BufferedImage** (package `java.awt.image`) object. Lines 38–39 create the **BufferedImage** object. Class **BufferedImage** can be used to produce images in color and grayscale. This particular **BufferedImage** is 10 pixels wide and 10 pixels tall (as specified by the first two arguments of the constructor). The third argument **BufferedImage.TYPE\_INT\_RGB** indicates that the image is stored in color using the RGB color scheme.

To create the rounded rectangle’s fill pattern, we must first draw into the **BufferedImage**. Line 42 creates a **Graphics2D** object (by calling **BufferedImage** method **createGraphics**) that can be used to draw into the **BufferedImage**. Lines 43–50 use methods `setColor`, `fillRect` and `drawRect` to create the pattern.

Lines 53–54 set the **Paint** object to a new **TexturePaint** (package `java.awt`) object. A **TexturePaint** object uses the image stored in its associated **BufferedImage** (the first constructor argument) as the fill texture for a filled-in shape. The second argument specifies the **Rectangle** area from the **BufferedImage** that will be replicated through the texture. In this case, the **Rectangle** is the same size as the **BufferedImage**. However, a smaller portion of the **BufferedImage** can be used.

Lines 55–56 use **Graphics2D** method `fill` to draw a filled **Shape** object—in this case, a **RoundRectangle2D.Double**. The constructor for class **RoundRectangle2D.Double** receives six arguments specifying the rectangle dimensions and the arc width and arc height used to determine the rounding of the corners.

### *Arcs*

Next we draw a pie-shaped arc with a thick white line. Line 59 sets the **Paint** object to `Color.WHITE`. Line 60 sets the **Stroke** object to a new **BasicStroke** for a line 6 pixels wide. Lines 61–62 use **Graphics2D** method `draw` to draw a **Shape** object—in this case, an **Arc2D.Double**. The **Arc2D.Double** constructor’s first four arguments specify the upper-left *x*-coordinate, upper-left *y*-coordinate, width and height of the bounding rectangle for the arc. The fifth argument specifies the start angle. The sixth argument specifies the arc angle. The last argument specifies how the arc is closed. Constant **Arc2D.PIE** indicates that the arc is closed by drawing two lines—one line from the arc’s starting point to the center of the bounding rectangle and one line from the center of the bounding rectangle to the ending point. Class **Arc2D** provides two other static constants for specifying how the arc is closed. Constant **Arc2D.CHORD** draws a line from the starting point to the ending point. Constant **Arc2D.OPEN** specifies that the arc should *not* be closed.

### *Lines*

Finally, we draw two lines using **Line2D** objects—one solid and one dashed. Line 65 sets the **Paint** object to `Color.GREEN`. Line 66 uses **Graphics2D** method `draw` to draw a **Shape** object—in this case, an instance of class **Line2D.Double**. The **Line2D.Double** constructor’s arguments specify the starting coordinates and ending coordinates of the line.

Line 69 declares a one-element `float` array containing the value 10. This array describes the dashes in the dashed line. In this case, each dash will be 10 pixels long. To create dashes of different lengths in a pattern, simply provide the length of each dash as an element in the array. Line 70 sets the **Paint** object to `Color.YELLOW`. Lines 71–72 set the **Stroke** object to a new **BasicStroke**. The line will be 4 pixels wide and will have rounded

ends (**BasicStroke.CAP\_ROUND**). If lines join together (as in a rectangle at the corners), their joining will be rounded (**BasicStroke.JOIN\_ROUND**). The dashes argument specifies the dash lengths for the line. The last argument indicates the starting index in the dashes array for the first dash in the pattern. Line 73 then draws a line with the current Stroke.

### *Creating Your Own Shapes with General Paths*

Next we present a **general path**—a shape constructed from straight lines and complex curves. A general path is represented with an object of class **GeneralPath** (package `java.awt.geom`). The application of Figs. 15.31 and 15.32 demonstrates drawing a general path in the shape of a five-pointed star.

---

```

1 // Fig. 15.31: Shapes2JPanel.java
2 // Demonstrating a general path.
3 import java.awt.Color;
4 import java.awt.Graphics;
5 import java.awt.Graphics2D;
6 import java.awt.geom.GeneralPath;
7 import java.util.Random;
8 import javax.swing.JPanel;
9
10 public class Shapes2JPanel extends JPanel
11 {
12     // draw general paths
13     public void paintComponent( Graphics g )
14     {
15         super.paintComponent( g ); // call superclass's paintComponent
16         Random random = new Random(); // get random number generator
17
18         int[] xPoints = { 55, 67, 109, 73, 83, 55, 27, 37, 1, 43 };
19         int[] yPoints = { 0, 36, 36, 54, 96, 72, 96, 54, 36, 36 };
20
21         Graphics2D g2d = ( Graphics2D ) g;
22         GeneralPath star = new GeneralPath(); // create GeneralPath object
23
24         // set the initial coordinate of the General Path
25         star.moveTo( xPoints[ 0 ], yPoints[ 0 ] );
26
27         // create the star--this does not draw the star
28         for ( int count = 1; count < xPoints.length; count++ )
29             star.lineTo( xPoints[ count ], yPoints[ count ] );
30
31         star.closePath(); // close the shape
32
33         g2d.translate( 150, 150 ); // translate the origin to (150, 150)
34
35         // rotate around origin and draw stars in random colors
36         for ( int count = 1; count <= 20; count++ )
37         {
38             g2d.rotate( Math.PI / 10.0 ); // rotate coordinate system
39

```

---

**Fig. 15.31** | Java 2D general paths. (Part 1 of 2.)

```

40         // set random drawing color
41         g2d.setColor( new Color( random.nextInt( 256 ),
42             random.nextInt( 256 ), random.nextInt( 256 ) ) );
43
44         g2d.fill( star ); // draw filled star
45     } // end for
46 } // end method paintComponent
47 } // end class Shapes2JPanel

```

**Fig. 15.31** | Java 2D general paths. (Part 2 of 2.)

```

1 // Fig. 15.32: Shapes2.java
2 // Demonstrating a general path.
3 import java.awt.Color;
4 import javax.swing.JFrame;
5
6 public class Shapes2
7 {
8     // execute application
9     public static void main( String[] args )
10    {
11        // create frame for Shapes2JPanel
12        JFrame frame = new JFrame( "Drawing 2D Shapes" );
13        frame.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
14
15        Shapes2JPanel shapes2JPanel = new Shapes2JPanel();
16        frame.add( shapes2JPanel ); // add shapes2JPanel to frame
17        frame.setBackground( Color.WHITE ); // set frame background color
18        frame.setSize( 315, 330 ); // set frame size
19        frame.setVisible( true ); // display frame
20    } // end main
21 } // end class Shapes2

```

**Fig. 15.32** | Creating JFrame to display stars.

Lines 18–19 declare two `int` arrays representing the  $x$ - and  $y$ -coordinates of the points in the star. Line 22 creates `GeneralPath` object `star`. Line 25 uses `GeneralPath` method `moveTo` to specify the first point in the star. The `for` statement in lines 28–29 uses `GeneralPath` method `lineTo` to draw a line to the next point in the star. Each new call to

`lineTo` draws a line from the previous point to the current point. Line 31 uses `GeneralPath` method `closePath` to draw a line from the last point to the point specified in the last call to `moveTo`. This completes the general path.

Line 33 uses `Graphics2D` method `translate` to move the drawing origin to location (150, 150). All drawing operations now use location (150, 150) as (0, 0).

The `for` statement in lines 36–45 draws the star 20 times by rotating it around the new origin point. Line 38 uses `Graphics2D` method `rotate` to rotate the next displayed shape. The argument specifies the rotation angle in radians (with  $360^\circ = 2\pi$  radians). Line 44 uses `Graphics2D` method `fill` to draw a filled version of the star.

## 15.9 Wrap-Up

In this chapter, you learned how to use Java's graphics capabilities to produce colorful drawings. You learned how to specify the location of an object using Java's coordinate system, and how to draw on a window using the `paintComponent` method. You were introduced to class `Color`, and you learned how to use this class to specify different colors using their RGB components. You used the `JColorChooser` dialog to allow users to select colors in a program. You then learned how to work with fonts when drawing text on a window. You learned how to create a `Font` object from a font name, style and size, as well as how to access the metrics of a font. From there, you learned how to draw various shapes on a window, such as rectangles (regular, rounded and 3D), ovals and polygons, as well as lines and arcs. You then used the Java 2D API to create more complex shapes and to fill them with gradients or patterns. The chapter concluded with a discussion of general paths, used to construct shapes from straight lines and complex curves. In the next chapter, we discuss class `String` and its methods. We introduce regular expressions for pattern matching in strings and demonstrate how to validate user input with regular expressions.

## Summary

### Section 15.1 Introduction

- Java's coordinate system (p. 632) is a scheme for identifying every point (p. 643) on the screen.
- A coordinate pair (p. 632) has an *x*-coordinate (horizontal) and a *y*-coordinate (vertical).
- Coordinates are used to indicate where graphics should be displayed on a screen.
- Coordinate units are measured in pixels (p. 632). A pixel is a display monitor's smallest unit of resolution.

### Section 15.2 Graphics Contexts and Graphics Objects

- A Java graphics context (p. 634) enables drawing on the screen.
- Class `Graphics` (p. 632) contains methods for drawing strings, lines, rectangles and other shapes. Methods are also included for font manipulation and color manipulation.
- A `Graphics` object manages a graphics context and draws pixels on the screen that represent text and other graphical objects, e.g., lines, ellipses, rectangles and other polygons (p. 654).
- Class `Graphics` is an abstract class. Each Java implementation has a `Graphics` subclass that provides drawing capabilities. This implementation is hidden from us by class `Graphics`, which supplies the interface that enables us to use graphics in a platform-independent manner.

- Method `paintComponent` can be used to draw graphics in any `JComponent` component.
- Method `paintComponent` receives a `Graphics` object that is passed to the method by the system when a lightweight Swing component needs to be repainted.
- When an application executes, the application container calls method `paintComponent`. For `paintComponent` to be called again, an event must occur.
- When a `JComponent` is displayed, its `paintComponent` method is called.
- Calling method `repaint` (p. 635) on a component updates the graphics drawn on that component.

### Section 15.3 Color Control

- Class `Color` (p. 632) declares methods and constants for manipulating colors in a Java program.
- Every color is created from a red, a green and a blue component. Together these components are called RGB values (p. 636). The RGB components specify the amount of red, green and blue in a color, respectively. The larger the RGB value, the greater the amount of that particular color.
- `Color` methods `getRed`, `getGreen` and `getBlue` (p. 636) return `int` values from 0 to 255 representing the amount of red, green and blue, respectively.
- `Graphics` method `getColor` (p. 636) returns a `Color` object with the current drawing color.
- `Graphics` method `setColor` (p. 636) sets the current drawing color.
- `Graphics` method `fillRect` (p. 636) draws a rectangle filled by the `Graphics` object's current color.
- `Graphics` method `drawString` (p. 638) draws a `String` in the current color.
- The `JColorChooser` GUI component (p. 639) enables application users to select colors.
- `JColorChooser` static method `showDialog` (p. 641) displays a modal `JColorChooser` dialog.

### Section 15.4 Manipulating Fonts

- Class `Font` (p. 632) contains methods and constants for manipulating fonts.
- Class `Font`'s constructor takes three arguments—the font name (p. 643), font style and font size.
- A `Font`'s font style can be `Font.PLAIN`, `Font.ITALIC` or `Font.BOLD` (each is a static field of class `Font`). Font styles can be used in combination (e.g., `Font.ITALIC + Font.BOLD`).
- The font size is measured in points. A point is 1/72 of an inch.
- `Graphics` method `setFont` (p. 643) sets the drawing font in which text will be displayed.
- `Font` method `getStyle` (p. 645) returns an integer value representing the current `Font`'s style.
- `Font` method `getSize` (p. 643) returns the font size in points.
- `Font` method `getName` (p. 643) returns the current font name as a string.
- `Font` method `getFamily` (p. 645) returns the name of the font family to which the current font belongs. The name of the font family is platform specific.
- Class `FontMetrics` (p. 645) contains methods for obtaining font information.
- `Font` metrics (p. 645) include height, descent and leading.

### Section 15.5 Drawing Lines, Rectangles and Ovals

- `Graphics` methods `fillRoundRect` (p. 649) and `drawRoundRect` (p. 649) draw rectangles with rounded corners.
- `Graphics` methods `draw3DRect` (p. 651) and `fill3DRect` (p. 651) draw three-dimensional rectangles.
- `Graphics` methods `drawOval` (p. 651) and `fillOval` (p. 651) draw ovals.

### Section 15.6 Drawing Arcs

- An arc (p. 651) is drawn as a portion of an oval.

- Arcs sweep from a starting angle by the number of degrees specified by their arc angle (p. 651).
- Graphics methods `drawArc` (p. 651) and `fillArc` (p. 651) are used for drawing arcs.

### Section 15.7 Drawing Polygons and Polylines

- Class `Polygon` contains methods for creating polygons.
- Polygons are closed multisided shapes composed of straight-line segments.
- Polylines (p. 654) are a sequence of connected points.
- Graphics method `drawPolyline` (p. 656) displays a series of connected lines.
- Graphics methods `drawPolygon` (p. 656) and `fillPolygon` (p. 657) are used to draw polygons.
- `Polygon` method `addPoint` (p. 657) adds pairs of *x*- and *y*-coordinates to the `Polygon`.

### Section 15.8 Java 2D API

- The Java 2D API (p. 657) provides advanced two-dimensional graphics capabilities.
- Class `Graphics2D` (p. 632)—a subclass of `Graphics`—is used for drawing with the Java 2D API.
- The Java 2D API's classes for drawing shapes include `Line2D.Double`, `Rectangle2D.Double`, `RoundRectangle2D.Double`, `Arc2D.Double` and `Ellipse2D.Double` (p. 657).
- Class `GradientPaint` (p. 632) helps draw a shape in gradually changing colors—called a gradient (p. 660).
- `Graphics2D` method `fill` (p. 660) draws a filled object of any type that implements interface `Shape` (p. 660).
- Class `BasicStroke` (p. 632) helps specify the drawing characteristics of lines.
- `Graphics2D` method `draw` (p. 660) is used to draw a `Shape` object.
- Classes `GradientPaint` and `TexturePaint` (p. 632) help specify the characteristics for filling shapes with colors or patterns.
- A general path (p. 662) is a shape constructed from straight lines and complex curves and is represented with an object of class `GeneralPath` (p. 662).
- `GeneralPath` method `moveTo` (p. 663) specifies the first point in a general path.
- `GeneralPath` method `lineTo` (p. 663) draws a line to the next point in the path. Each new call to `lineTo` draws a line from the previous point to the current point.
- `GeneralPath` method `closePath` (p. 664) draws a line from the last point to the point specified in the last call to `moveTo`. This completes the general path.
- `Graphics2D` method `translate` (p. 664) is used to move the drawing origin to a new location.
- `Graphics2D` method `rotate` (p. 664) is used to rotate the next displayed shape.

## Self-Review Exercises

- 15.1** Fill in the blanks in each of the following statements:
- In Java 2D, method \_\_\_\_\_ of class \_\_\_\_\_ sets the characteristics of a line used to draw a shape.
  - Class \_\_\_\_\_ helps specify the fill for a shape such that the fill gradually changes from one color to another.
  - The \_\_\_\_\_ method of class `Graphics` draws a line between two points.
  - RGB is short for \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - Font sizes are measured in units called \_\_\_\_\_.
  - Class \_\_\_\_\_ helps specify the fill for a shape using a pattern drawn in a `BufferedImage`.

- 15.2** State whether each of the following is *true* or *false*. If *false*, explain why.
- The first two arguments of `Graphics` method `drawOval` specify the center coordinate of the oval.
  - In the Java coordinate system,  $x$ -coordinates increase from left to right and  $y$ -coordinates from top to bottom.
  - `Graphics` method `fillPolygon` draws a filled polygon in the current color.
  - `Graphics` method `drawArc` allows negative angles.
  - `Graphics` method `getSize` returns the size of the current font in centimeters.
  - Pixel coordinate  $(0, 0)$  is located at the exact center of the monitor.
- 15.3** Find the error(s) in each of the following and explain how to correct them. Assume that `g` is a `Graphics` object.
- `g.setFont( "SansSerif" );`
  - `g.erase( x, y, w, h ); // clear rectangle at (x, y)`
  - `Font f = new Font( "Serif", Font.BOLDITALIC, 12 );`
  - `g.setColor( 255, 255, 0 ); // change color to yellow`

## Answers to Self-Review Exercises

- 15.1** a) `setStroke`, `Graphics2D`. b) `GradientPaint`. c) `drawLine`. d) red, green, blue. e) points. f) `TexturePaint`.
- 15.2** a) False. The first two arguments specify the upper-left corner of the bounding rectangle.  
 b) True.  
 c) True.  
 d) True.  
 e) False. Font sizes are measured in points.  
 f) False. The coordinate  $(0,0)$  corresponds to the upper-left corner of a GUI component on which drawing occurs.
- 15.3** a) The `setFont` method takes a `Font` object as an argument—not a `String`.  
 b) The `Graphics` class does not have an `erase` method. The `clearRect` method should be used.  
 c) `Font.BOLDITALIC` is not a valid font style. To get a bold italic font, use `Font.BOLD + Font.ITALIC`.  
 d) Method `setColor` takes a `Color` object as an argument, not three integers.

## Exercises

- 15.4** Fill in the blanks in each of the following statements:
- Class \_\_\_\_\_ of the Java 2D API is used to draw ovals.
  - Methods `draw` and `fill` of class `Graphics2D` require an object of type \_\_\_\_\_ as their argument.
  - The three constants that specify font style are \_\_\_\_\_, \_\_\_\_\_ and \_\_\_\_\_.
  - `Graphics2D` method \_\_\_\_\_ sets the painting color for Java 2D shapes.
- 15.5** State whether each of the following is *true* or *false*. If *false*, explain why.
- `Graphics` method `drawPolygon` automatically connects the endpoints of the polygon.
  - `Graphics` method `drawLine` draws a line between two points.
  - `Graphics` method `fillArc` uses degrees to specify the angle.
  - In the Java coordinate system, values on the  $y$ -axis increase from left to right.
  - `Graphics` inherits directly from class `Object`.
  - `Graphics` is an abstract class.
  - The `Font` class inherits directly from class `Graphics`.

**15.6** (*Concentric Circles Using Method drawArc*) Write an application that draws a series of eight concentric circles. The circles should be separated by 10 pixels. Use Graphics method drawArc.

**15.7** (*Concentric Circles Using Class Ellipse2D.Double*) Modify your solution to Exercise 15.6 to draw the ovals by using class Ellipse2D.Double and method draw of class Graphics2D.

**15.8** (*Random Lines Using Class Line2D.Double*) Modify your solution to Exercise 15.7 to draw random lines in random colors and random line thicknesses. Use class Line2D.Double and method draw of class Graphics2D to draw the lines.

**15.9** (*Random Triangles*) Write an application that displays randomly generated triangles in different colors. Each triangle should be filled with a different color. Use class GeneralPath and method fill of class Graphics2D to draw the triangles.

**15.10** (*Random Characters*) Write an application that randomly draws characters in different fonts, sizes and colors.

**15.11** (*Grid Using Method drawLine*) Write an application that draws an 8-by-8 grid. Use Graphics method drawLine.

**15.12** (*Grid Using Class Line2D.Double*) Modify your solution to Exercise 15.11 to draw the grid using instances of class Line2D.Double and method draw of class Graphics2D.

**15.13** (*Grid Using Method drawRect*) Write an application that draws a 10-by-10 grid. Use the Graphics method drawRect.

**15.14** (*Grid Using Class Rectangle2D.Double*) Modify your solution to Exercise 15.13 to draw the grid by using class Rectangle2D.Double and method draw of class Graphics2D.

**15.15** (*Drawing Tetrahedrons*) Write an application that draws a tetrahedron (a three-dimensional shape with four triangular faces). Use class GeneralPath and method draw of class Graphics2D.

**15.16** (*Drawing Cubes*) Write an application that draws a cube. Use class GeneralPath and method draw of class Graphics2D.

**15.17** (*Circles Using Class Ellipse2D.Double*) Write an application that asks the user to input the radius of a circle as a floating-point number and draws the circle, as well as the values of the circle's diameter, circumference and area. Use the value 3.14159 for  $\pi$ . [Note: You may also use the predefined constant Math.PI for the value of  $\pi$ . This constant is more precise than the value 3.14159. Class Math is declared in the java.lang package, so you need not import it.] Use the following formulas ( $r$  is the radius):

$$\begin{aligned} \text{diameter} &= 2r \\ \text{circumference} &= 2\pi r \\ \text{area} &= \pi r^2 \end{aligned}$$

The user should also be prompted for a set of coordinates in addition to the radius. Then draw the circle and display its diameter, circumference and area, using an Ellipse2D.Double object to represent the circle and method draw of class Graphics2D to display it.

**15.18** (*Screen Saver*) Write an application that simulates a screen saver. The application should randomly draw lines using method drawLine of class Graphics. After drawing 100 lines, the application should clear itself and start drawing lines again. To allow the program to draw continuously, place a call to repaint as the last line in method paintComponent. Do you notice any problems with this on your system?

**15.19** (*Screen Saver Using Timer*) Package javax.swing contains a class called Timer that is capable of calling method actionPerformed of interface ActionListener at a fixed time interval (specified in milliseconds). Modify your solution to Exercise 15.18 to remove the call to repaint from method paintComponent. Declare your class to implement ActionListener. (The actionPerformed

method should simply call `repaint()`.) Declare an instance variable of type `Timer` called `timer` in your class. In the constructor for your class, write the following statements:

```
timer = new Timer( 1000, this );
timer.start();
```

This creates an instance of class `Timer` that will call `this` object's `actionPerformed` method every 1000 milliseconds (i.e., every second).

**15.20** (*Screen Saver for a Random Number of Lines*) Modify your solution to Exercise 15.19 to enable the user to enter the number of random lines that should be drawn before the application clears itself and starts drawing lines again. Use a `JTextField` to obtain the value. The user should be able to type a new number into the `JTextField` at any time during the program's execution. Use an inner class to perform event handling for the `JTextField`.

**15.21** (*Screen Saver with Shapes*) Modify your solution to Exercise 15.19 such that it uses random-number generation to choose different shapes to display. Use methods of class `Graphics`.

**15.22** (*Screen Saver Using the Java 2D API*) Modify your solution to Exercise 15.21 to use classes and drawing capabilities of the Java 2D API. Draw shapes like rectangles and ellipses, with randomly generated gradients. Use class `GradientPaint` to generate the gradient.

**15.23** (*Turtle Graphics*) Modify your solution to Exercise 7.21—*Turtle Graphics*—to add a graphical user interface using `JTextFields` and `JButtons`. Draw lines rather than asterisks (\*). When the turtle graphics program specifies a move, translate the number of positions into a number of pixels on the screen by multiplying the number of positions by 10 (or any value you choose). Implement the drawing with Java 2D API features.

**15.24** (*Knight's Tour*) Produce a graphical version of the Knight's Tour problem (Exercise 7.22, Exercise 7.23 and Exercise 7.26). As each move is made, the appropriate cell of the chessboard should be updated with the proper move number. If the result of the program is a *full tour* or a *closed tour*, the program should display an appropriate message. If you like, use class `Timer` (see Exercise 15.19) to help animate the Knight's Tour.

**15.25** (*Tortoise and Hare*) Produce a graphical version of the *Tortoise and Hare* simulation (Exercise 7.28). Simulate the mountain by drawing an arc that extends from the bottom-left corner of the window to the top-right corner. The tortoise and the hare should race up the mountain. Implement the graphical output to actually print the tortoise and the hare on the arc for every move. [*Hint*: Extend the length of the race from 70 to 300 to allow yourself a larger graphics area.]

**15.26** (*Drawing Spirals*) Write an application that uses `Graphics` method `drawPolyline` to draw a spiral similar to the one shown in Fig. 15.33.

**Fig. 15.33** | Spiral drawn using method `drawPolyline`.

**15.27 (Pie Chart)** Write a program that inputs four numbers and graphs them as a pie chart. Use class `Arc2D.Double` and method `fill` of class `Graphics2D` to perform the drawing. Draw each piece of the pie in a separate color.

**15.28 (Selecting Shapes)** Write an application that allows the user to select a shape from a `JComboBox` and draws it 20 times with random locations and dimensions in method `paintComponent`. The first item in the `JComboBox` should be the default shape that is displayed the first time `paintComponent` is called.

**15.29 (Random Colors)** Modify Exercise 15.28 to draw each of the 20 randomly sized shapes in a randomly selected color. Use all 13 predefined `Color` objects in an array of `Colors`.

**15.30 (JColorChooser Dialog)** Modify Exercise 15.28 to allow the user to select the color in which shapes should be drawn from a `JColorChooser` dialog.

### *(Optional) GUI and Graphics Case Study: Adding Java 2D*

**15.31** Java 2D introduces many new capabilities for creating unique and impressive graphics. We'll add a small subset of these features to the drawing application you created in Exercise 14.17. In this version, you'll enable the user to specify gradients for filling shapes and to change stroke characteristics for drawing lines and outlines of shapes. The user will be able to choose which colors compose the gradient and set the width and dash length of the stroke.

First, you must update the `MyShape` hierarchy to support Java 2D functionality. Make the following changes in class `MyShape`:

- a) Change abstract method `draw`'s parameter type from `Graphics` to `Graphics2D`.
- b) Change all variables of type `Color` to type `Paint` to enable support for gradients. [*Note:* Recall that class `Color` implements interface `Paint`.]
- c) Add an instance variable of type `Stroke` in class `MyShape` and a `Stroke` parameter in the constructor to initialize the new instance variable. The default stroke should be an instance of class `BasicStroke`.

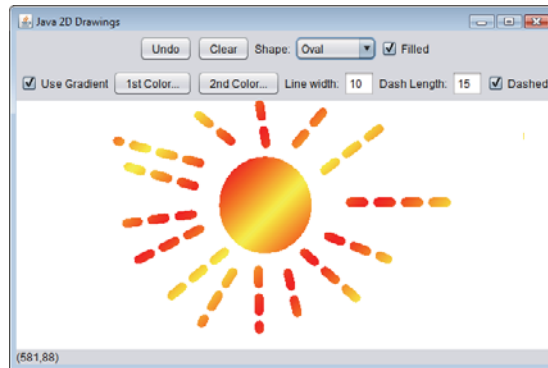

Classes `MyLine`, `MyBoundedShape`, `MyOval` and `MyRectangle` should each add a `Stroke` parameter to their constructors. In the `draw` methods, each shape should set the `Paint` and the `Stroke` before drawing or filling a shape. Since `Graphics2D` is a subclass of `Graphics`, we can continue to use `Graphics` methods `drawLine`, `drawOval`, `fillOval`, and so on, to draw the shapes. When these methods are called, they'll draw the appropriate shape using the specified `Paint` and `Stroke` settings.

Next, you'll update the `DrawPanel` to handle the Java 2D features. Change all `Color` variables to `Paint` variables. Declare an instance variable `currentStroke` of type `Stroke` and provide a *set* method for it. Update the calls to the individual shape constructors to include the `Paint` and `Stroke` arguments. In method `paintComponent`, cast the `Graphics` reference to type `Graphics2D` and use the `Graphics2D` reference in each call to `MyShape` method `draw`.

Next, make the new Java 2D features accessible from the GUI. Create a `JPanel` of GUI components for setting the Java 2D options. Add these components at the top of the `DrawFrame` below the panel that currently contains the standard shape controls (see Fig. 15.34). These GUI components should include:

- a) A check box to specify whether to paint using a gradient.
- b) Two `JButtons` that each show a `JColorChooser` dialog to allow the user to choose the first and second color in the gradient. (These will replace the `JComboBox` used for choosing the color in Exercise 14.17.)
- c) A text field for entering the `Stroke` width.
- d) A text field for entering the `Stroke` dash length.
- e) A check box for selecting whether to draw a dashed or solid line.

If the user selects to draw with a gradient, set the `Paint` on the `DrawPanel` to be a gradient of the two colors chosen by the user. The expression

**Fig. 15.34** | Drawing with Java 2D.

```
new GradientPaint( 0, 0, color1, 50, 50, color2, true ) )
```

creates a `GradientPaint` that cycles diagonally from the upper-left to the bottom-right every 50 pixels. Variables `color1` and `color2` represent the colors chosen by the user. If the user does not select to use a gradient, then simply set the `Paint` on the `DrawPane1` to be the first `Color` chosen by the user.

For strokes, if the user chooses a solid line, then create the `Stroke` with the expression

```
new BasicStroke( width, BasicStroke.CAP_ROUND, BasicStroke.JOIN_ROUND )
```

where variable `width` is the width specified by the user in the line-width text field. If the user chooses a dashed line, then create the `Stroke` with the expression

```
new BasicStroke( width, BasicStroke.CAP_ROUND, BasicStroke.JOIN_ROUND,
    10, dashes, 0 )
```

where `width` again is the width in the line-width field, and `dashes` is an array with one element whose value is the length specified in the dash-length field. The `Panel` and `Stroke` objects should be passed to the shape object's constructor when the shape is created in `DrawPane1`.

## Making a Difference

**15.32** (*Large-Type Displays for People with Low Vision*) The accessibility of computers and the Internet to all people, regardless of disabilities, is becoming more important as these tools play increasing roles in our personal and business lives. According to a recent estimate by the World Health Organization ([www.who.int/mediacentre/factsheets/fs282/en/](http://www.who.int/mediacentre/factsheets/fs282/en/)), 124 million people worldwide have low vision. To learn more about low vision, check out the GUI-based low-vision simulation at [www.webaim.org/simulations/lowvision.php](http://www.webaim.org/simulations/lowvision.php). People with low vision might prefer to choose a font and/or a larger font size when reading electronic documents and web pages. Java has five built-in “logical” fonts that are guaranteed to be available in any Java implementation, including `Serif`, `Sans-serif` and `Monospaced`. Write a GUI application that provides a `JTextArea` in which the user can type text. Allow the user to select `Serif`, `Sans-serif` or `Monospaced` from a `JComboBox`. Provide a `Bold` `JCheckBox`, which, if checked, makes the text bold. Include `Increase Font Size` and `Decrease Font Size` `JButtons` that allow the user to scale the size of the font up or down, respectively, by one point at a time. Start with a font size of 18 points. For the purposes of this exercise, set the font size on the `JComboBox`, `JButtons` and `JCheckBox` to 20 points so that a person with low vision will be able to read the text on them.

## Strings, Characters and Regular Expressions

*The chief defect of Henry King  
Was chewing little bits of string.*

—Hilaire Belloc

*Vigorous writing is concise. A  
sentence should contain no  
unnecessary words, a paragraph  
no unnecessary sentences.*

—William Strunk, Jr.

*I have made this letter longer  
than usual, because I lack the  
time to make it short.*

—Blaise Pascal

### Objectives

In this chapter you'll learn:

- To create and manipulate immutable character-string objects of class `String`.
- To create and manipulate mutable character-string objects of class `StringBuilder`.
- To create and manipulate objects of class `Character`.
- To break a `String` object into tokens using `String` method `split`.
- To use regular expressions to validate `String` data entered into an application.

- 16.1 Introduction
- 16.2 Fundamentals of Characters and Strings
- 16.3 Class `String`
  - 16.3.1 `String` Constructors
  - 16.3.2 `String` Methods `length`, `charAt` and `getChars`
  - 16.3.3 Comparing Strings
  - 16.3.4 Locating Characters and Substrings in Strings
  - 16.3.5 Extracting Substrings from Strings
  - 16.3.6 Concatenating Strings
  - 16.3.7 Miscellaneous `String` Methods
  - 16.3.8 `String` Method `valueOf`
- 16.4 Class `StringBuilder`
  - 16.4.1 `StringBuilder` Constructors
  - 16.4.2 `StringBuilder` Methods `length`, `capacity`, `setLength` and `ensureCapacity`
  - 16.4.3 `StringBuilder` Methods `charAt`, `setCharAt`, `getChars` and `reverse`
  - 16.4.4 `StringBuilder` append Methods
  - 16.4.5 `StringBuilder` Insertion and Deletion Methods
- 16.5 Class `Character`
- 16.6 Tokenizing Strings
- 16.7 Regular Expressions, Class `Pattern` and Class `Matcher`
- 16.8 Wrap-Up

*Summary | Self-Review Exercises | Answers to Self-Review Exercises | Exercises | Special Section: Advanced String-Manipulation Exercises | Special Section: Challenging String-Manipulation Projects | Making a Difference*

## 16.1 Introduction

This chapter introduces Java's string- and character-processing capabilities. The techniques discussed here are appropriate for validating program input, displaying information to users and other text-based manipulations. They're also appropriate for developing text editors, word processors, page-layout software, computerized typesetting systems and other kinds of text-processing software. We've presented several string-processing capabilities in earlier chapters. This chapter discusses in detail the capabilities of classes `String`, `StringBuilder` and `Character` from the `java.lang` package. These classes provide the foundation for string and character manipulation in Java.

The chapter also discusses regular expressions that provide applications with the capability to validate input. The functionality is located in the `String` class along with classes `Matcher` and `Pattern` located in the `java.util.regex` package.

## 16.2 Fundamentals of Characters and Strings

Characters are the fundamental building blocks of Java source programs. Every program is composed of a sequence of characters that—when grouped together meaningfully—are interpreted by the Java compiler as a series of instructions used to accomplish a task. A program may contain **character literals**. A character literal is an integer value represented as a character in single quotes. For example, `'z'` represents the integer value of `z`, and `'\n'` represents the integer value of newline. The value of a character literal is the integer value of the character in the **Unicode character set**. Appendix B presents the integer equivalents of the characters in the ASCII character set, which is a subset of Unicode (discussed in Appendix L).

Recall from Section 2.2 that a string is a sequence of characters treated as a single unit. A string may include letters, digits and various **special characters**, such as `+`, `-`, `*`, `/` and `$`.

A string is an object of class `String`. **String literals** (stored in memory as `String` objects) are written as a sequence of characters in double quotation marks, as in:

|                          |                      |
|--------------------------|----------------------|
| "John Q. Doe"            | (a name)             |
| "9999 Main Street"       | (a street address)   |
| "Waltham, Massachusetts" | (a city and state)   |
| "(201) 555-1212"         | (a telephone number) |

A string may be assigned to a `String` reference. The declaration

```
String color = "blue";
```

initializes `String` variable `color` to refer to a `String` object that contains the string "blue".

### Performance Tip 16.1

To conserve memory, Java treats all string literals with the same contents as a single `String` object that has many references to it.

## 16.3 Class String

Class `String` is used to represent strings in Java. The next several subsections cover many of class `String`'s capabilities.

### 16.3.1 String Constructors

Class `String` provides constructors for initializing `String` objects in a variety of ways. Four of the constructors are demonstrated in the main method of Fig. 16.1.

Line 12 instantiates a new `String` using class `String`'s no-argument constructor and assigns its reference to `s1`. The new `String` object contains no characters (i.e., the **empty**

```

1 // Fig. 16.1: StringConstructors.java
2 // String class constructors.
3
4 public class StringConstructors
5 {
6     public static void main( String[] args )
7     {
8         char[] charArray = { 'b', 'i', 'r', 't', 'h', ' ', 'd', 'a', 'y' };
9         String s = new String( "hello" );
10
11         // use String constructors
12         String s1 = new String();
13         String s2 = new String( s );
14         String s3 = new String( charArray );
15         String s4 = new String( charArray, 6, 3 );
16
17         System.out.printf(
18             "s1 = %s\ns2 = %s\ns3 = %s\ns4 = %s\n",
19             s1, s2, s3, s4 ); // display strings
20     } // end main
21 } // end class StringConstructors

```

**Fig. 16.1** | String class constructors. (Part 1 of 2.)

```
s1 =
s2 = hello
s3 = birth day
s4 = day
```

**Fig. 16.1** | String class constructors. (Part 2 of 2.)

**string**, which can also be represented as `""`) and has a length of 0. Line 13 instantiates a new `String` object using class `String`'s constructor that takes a `String` object as an argument and assigns its reference to `s2`. The new `String` object contains the same sequence of characters as the `String` object `s` that's passed as an argument to the constructor.

### Software Engineering Observation 16.1

*It's not necessary to copy an existing `String` object. `String` objects are **immutable**—their character contents cannot be changed after they're created, because class `String` does not provide methods that allow the contents of a `String` object to be modified.*

Line 14 instantiates a new `String` object and assigns its reference to `s3` using class `String`'s constructor that takes a `char` array as an argument. The new `String` object contains a copy of the characters in the array.

Line 15 instantiates a new `String` object and assigns its reference to `s4` using class `String`'s constructor that takes a `char` array and two integers as arguments. The second argument specifies the starting position (the offset) from which characters in the array are accessed. Remember that the first character is at position 0. The third argument specifies the number of characters (the count) to access in the array. The new `String` object is formed from the accessed characters. If the offset or the count specified as an argument results in accessing an element outside the bounds of the character array, a `StringIndexOutOfBoundsException` is thrown.

### Common Programming Error 16.1

*Accessing a character outside the bounds of a `String` (i.e., an index less than 0 or an index greater than or equal to the `String`'s length) results in a `StringIndexOutOfBoundsException`.*

## 16.3.2 String Methods `length`, `charAt` and `getChars`

`String` methods **`length`**, **`charAt`** and **`getChars`** return the length of a `String`, obtain the character at a specific location in a `String` and retrieve a set of characters from a `String` as a `char` array, respectively. Figure 16.2 demonstrates each of these methods.

```
1 // Fig. 16.2: StringMiscellaneous.java
2 // This application demonstrates the length, charAt and getChars
3 // methods of the String class.
4
5 public class StringMiscellaneous
6 {
```

**Fig. 16.2** | String methods `length`, `charAt` and `getChars`. (Part 1 of 2.)

```

7   public static void main( String[] args )
8   {
9       String s1 = "hello there";
10      char[] charArray = new char[ 5 ];
11
12      System.out.printf( "s1: %s", s1 );
13
14      // test length method
15      System.out.printf( "\nLength of s1: %d", s1.length() );
16
17      // loop through characters in s1 with charAt and display reversed
18      System.out.print( "\nThe string reversed is: " );
19
20      for ( int count = s1.length() - 1; count >= 0; count-- )
21          System.out.printf( "%c ", s1.charAt( count ) );
22
23      // copy characters from string into charArray
24      s1.getChars( 0, 5, charArray, 0 );
25      System.out.print( "\nThe character array is: " );
26
27      for ( char character : charArray )
28          System.out.print( character );
29
30      System.out.println();
31  } // end main
32 } // end class StringMiscellaneous

```

```

s1: hello there
Length of s1: 11
The string reversed is: e r e h t   o l l e h
The character array is: hello

```

**Fig. 16.2** | String methods `length`, `charAt` and `getChars`. (Part 2 of 2.)

Line 15 uses `String` method `length` to determine the number of characters in `String` `s1`. Like arrays, strings know their own length. However, unlike arrays, you access a `String`'s length via class `String`'s `length` method.

Lines 20–21 print the characters of the `String` `s1` in reverse order (and separated by spaces). `String` method `charAt` (line 21) returns the character at a specific position in the `String`. Method `charAt` receives an integer argument that's used as the index and returns the character at that position. Like arrays, the first element of a `String` is at position 0.

Line 24 uses `String` method `getChars` to copy the characters of a `String` into a character array. The first argument is the starting index from which characters are to be copied. The second argument is the index that's one past the last character to be copied from the `String`. The third argument is the character array into which the characters are to be copied. The last argument is the starting index where the copied characters are placed in the target character array. Next, lines 27–28 print the char array contents one character at a time.

### 16.3.3 Comparing Strings

Chapter 19 discusses sorting and searching arrays. Frequently, the information being sorted or searched consists of `Strings` that must be compared to place them into order or to

determine whether a string appears in an array (or other collection). Class `String` provides methods for comparing strings, as demonstrated in the next two examples.

To understand what it means for one string to be greater than or less than another, consider the process of alphabetizing a series of last names. No doubt, you'd place "Jones" before "Smith" because the first letter of "Jones" comes before the first letter of "Smith" in the alphabet. But the alphabet is more than just a list of 26 letters—it's an ordered set of characters. Each letter occurs in a specific position within the set. Z is more than just a letter of the alphabet—it's specifically the twenty-sixth letter of the alphabet.

How does the computer know that one letter "comes before" another? All characters are represented in the computer as numeric codes (see Appendix B). When the computer compares `Strings`, it actually compares the numeric codes of the characters in the `Strings`.

Figure 16.3 demonstrates `String` methods `equals`, `equalsIgnoreCase`, `compareTo` and `regionMatches` and using the equality operator `==` to compare `String` objects.

---

```

1 // Fig. 16.3: StringCompare.java
2 // String methods equals, equalsIgnoreCase, compareTo and regionMatches.
3
4 public class StringCompare
5 {
6     public static void main( String[] args )
7     {
8         String s1 = new String( "hello" ); // s1 is a copy of "hello"
9         String s2 = "goodbye";
10        String s3 = "Happy Birthday";
11        String s4 = "happy birthday";
12
13        System.out.printf(
14            "s1 = %s\ns2 = %s\ns3 = %s\ns4 = %s\n\n", s1, s2, s3, s4 );
15
16        // test for equality
17        if ( s1.equals( "hello" ) ) // true
18            System.out.println( "s1 equals \"hello\"" );
19        else
20            System.out.println( "s1 does not equal \"hello\"" );
21
22        // test for equality with ==
23        if ( s1 == "hello" ) // false; they are not the same object
24            System.out.println( "s1 is the same object as \"hello\"" );
25        else
26            System.out.println( "s1 is not the same object as \"hello\"" );
27
28        // test for equality (ignore case)
29        if ( s3.equalsIgnoreCase( s4 ) ) // true
30            System.out.printf( "%s equals %s with case ignored\n", s3, s4 );
31        else
32            System.out.println( "s3 does not equal s4" );
33

```

---

**Fig. 16.3** | String methods `equals`, `equalsIgnoreCase`, `compareTo` and `regionMatches`.  
(Part I of 2.)

```

34     // test compareTo
35     System.out.printf(
36         "\ns1.compareTo( s2 ) is %d", s1.compareTo( s2 ) );
37     System.out.printf(
38         "\ns2.compareTo( s1 ) is %d", s2.compareTo( s1 ) );
39     System.out.printf(
40         "\ns1.compareTo( s1 ) is %d", s1.compareTo( s1 ) );
41     System.out.printf(
42         "\ns3.compareTo( s4 ) is %d", s3.compareTo( s4 ) );
43     System.out.printf(
44         "\ns4.compareTo( s3 ) is %d\n\n", s4.compareTo( s3 ) );
45
46     // test regionMatches (case sensitive)
47     if ( s3.regionMatches( 0, s4, 0, 5 ) )
48         System.out.println( "First 5 characters of s3 and s4 match" );
49     else
50         System.out.println(
51             "First 5 characters of s3 and s4 do not match" );
52
53     // test regionMatches (ignore case)
54     if ( s3.regionMatches( true, 0, s4, 0, 5 ) )
55         System.out.println(
56             "First 5 characters of s3 and s4 match with case ignored" );
57     else
58         System.out.println(
59             "First 5 characters of s3 and s4 do not match" );
60     } // end main
61 } // end class StringCompare

```

```

s1 = hello
s2 = goodbye
s3 = Happy Birthday
s4 = happy birthday

s1 equals "hello"
s1 is not the same object as "hello"
Happy Birthday equals happy birthday with case ignored

s1.compareTo( s2 ) is 1
s2.compareTo( s1 ) is -1
s1.compareTo( s1 ) is 0
s3.compareTo( s4 ) is -32
s4.compareTo( s3 ) is 32

First 5 characters of s3 and s4 do not match
First 5 characters of s3 and s4 match with case ignored

```

**Fig. 16.3** | String methods equals, equalsIgnoreCase, compareTo and regionMatches.  
(Part 2 of 2.)

### ***String Method equals***

The condition at line 17 uses method equals to compare String s1 and the String literal "hello" for equality. Method equals (a method of class Object overridden in String) tests any two objects for equality—the strings contained in the two objects are identical.

The method returns true if the contents of the objects are equal, and false otherwise. The preceding condition is true because String s1 was initialized with the string literal "hello". Method equals uses a **lexicographical comparison**—it compares the integer Unicode values (see Appendix L, for more information) that represent each character in each String. Thus, if the String "hello" is compared with the string "HELLO", the result is false, because the integer representation of a lowercase letter is different from that of the corresponding uppercase letter.

### Comparing Strings with the == Operator

The condition at line 23 uses the equality operator == to compare String s1 for equality with the String literal "hello". When primitive-type values are compared with ==, the result is true if *both values are identical*. When references are compared with ==, the result is true if *both references refer to the same object in memory*. To compare the actual contents (or state information) of objects for equality, a method must be invoked. In the case of Strings, that method is equals. The preceding condition evaluates to false at line 23 because the reference s1 was initialized with the statement

```
s1 = new String( "hello" );
```

which creates a new String object with a copy of string literal "hello" and assigns the new object to variable s1. If s1 had been initialized with the statement

```
s1 = "hello";
```

which directly assigns the string literal "hello" to variable s1, the condition would be true. Remember that Java treats all string literal objects with the same contents as one String object to which there can be many references. Thus, lines 8, 17 and 23 all refer to the same String object "hello" in memory.

### Common Programming Error 16.2

*Comparing references with == can lead to logic errors, because == compares the references to determine whether they refer to the same object, not whether two objects have the same contents. When two identical (but separate) objects are compared with ==, the result will be false. When comparing objects to determine whether they have the same contents, use method equals.*

### String Method equalsIgnoreCase

If you're sorting Strings, you may compare them for equality with method equalsIgnoreCase, which ignores whether the letters in each String are uppercase or lowercase when performing the comparison. Thus, "hello" and "HELLO" compare as equal. Line 29 uses String method equalsIgnoreCase to compare String s3—Happy Birthday—for equality with String s4—happy birthday. The result of this comparison is true because the comparison ignores case sensitivity.

### String Method compareTo

Lines 35–44 use method compareTo to compare Strings. Method compareTo is declared in the Comparable interface and implemented in the String class. Line 36 compares String s1 to String s2. Method compareTo returns 0 if the Strings are equal, a negative number if the String that invokes compareTo is less than the String that's passed as an argument and a positive number if the String that invokes compareTo is greater than the

String that's passed as an argument. Method `compareTo` uses a lexicographical comparison—it compares the numeric values of corresponding characters in each String.

### *String Method `regionMatches`*

The condition at line 47 uses String method `regionMatches` to compare portions of two Strings for equality. The first argument is the starting index in the String that invokes the method. The second argument is a comparison String. The third argument is the starting index in the comparison String. The last argument is the number of characters to compare between the two Strings. The method returns true only if the specified number of characters are lexicographically equal.

Finally, the condition at line 54 uses a five-argument version of String method `regionMatches` to compare portions of two Strings for equality. When the first argument is true, the method ignores the case of the characters being compared. The remaining arguments are identical to those described for the four-argument `regionMatches` method.

### *String Methods `startsWith` and `endsWith`*

The next example (Fig. 16.4) demonstrates String methods `startsWith` and `endsWith`. Method `main` creates array `strings` containing "started", "starting", "ended" and "ending". The remainder of method `main` consists of three `for` statements that test the elements of the array to determine whether they start with or end with a particular set of characters.

---

```

1 // Fig. 16.4: StringStartEnd.java
2 // String methods startsWith and endsWith.
3
4 public class StringStartEnd
5 {
6     public static void main( String[] args )
7     {
8         String[] strings = { "started", "starting", "ended", "ending" };
9
10        // test method startsWith
11        for ( String string : strings )
12        {
13            if ( string.startsWith( "st" ) )
14                System.out.printf( "\"%s\" starts with \"st\"\n", string );
15        } // end for
16
17        System.out.println();
18
19        // test method startsWith starting from position 2 of string
20        for ( String string : strings )
21        {
22            if ( string.startsWith( "art", 2 ) )
23                System.out.printf(
24                    "\"%s\" starts with \"art\" at position 2\n", string );
25        } // end for
26
27        System.out.println();

```

---

**Fig. 16.4** | String methods `startsWith` and `endsWith`. (Part I of 2.)

```

28
29     // test method endsWith
30     for ( String string : strings )
31     {
32         if ( string.endsWith( "ed" ) )
33             System.out.printf( "\\\"%s\\\" ends with \\\"ed\\\"\\n", string );
34     } // end for
35 } // end main
36 } // end class StringStartEnd

```

```

"started" starts with "st"
"starting" starts with "st"

"started" starts with "art" at position 2
"starting" starts with "art" at position 2

"started" ends with "ed"
"ended" ends with "ed"

```

**Fig. 16.4** | String methods `startsWith` and `endsWith`. (Part 2 of 2.)

Lines 11–15 use the version of method `startsWith` that takes a `String` argument. The condition in the `if` statement (line 13) determines whether each `String` in the array starts with the characters "st". If so, the method returns `true` and the application prints that `String`. Otherwise, the method returns `false` and nothing happens.

Lines 20–25 use the `startsWith` method that takes a `String` and an integer as arguments. The integer specifies the index at which the comparison should begin in the `String`. The condition in the `if` statement (line 22) determines whether each `String` in the array has the characters "art" beginning with the third character in each `String`. If so, the method returns `true` and the application prints the `String`.

The third `for` statement (lines 30–34) uses method `endsWith`, which takes a `String` argument. The condition at line 32 determines whether each `String` in the array ends with the characters "ed". If so, the method returns `true` and the application prints the `String`.

### 16.3.4 Locating Characters and Substrings in Strings

Often it's useful to search a string for a character or set of characters. For example, if you're creating your own word processor, you might want to provide a capability for searching through documents. Figure 16.5 demonstrates the many versions of `String` methods `indexOf` and `lastIndexOf` that search for a specified character or substring in a `String`.

```

1 // Fig. 16.5: StringIndexMethods.java
2 // String searching methods indexOf and lastIndexOf.
3
4 public class StringIndexMethods
5 {
6     public static void main( String[] args )
7     {
8         String letters = "abcdefghijklmabcdefghijklm";

```

**Fig. 16.5** | String-searching methods `indexOf` and `lastIndexOf`. (Part 1 of 2.)

```

9
10 // test indexOf to locate a character in a string
11 System.out.printf(
12     "'c' is located at index %d\n", letters.indexOf( 'c' ) );
13 System.out.printf(
14     "'a' is located at index %d\n", letters.indexOf( 'a', 1 ) );
15 System.out.printf(
16     "'$' is located at index %d\n\n", letters.indexOf( '$' ) );
17
18 // test lastIndexOf to find a character in a string
19 System.out.printf( "Last 'c' is located at index %d\n",
20     letters.lastIndexOf( 'c' ) );
21 System.out.printf( "Last 'a' is located at index %d\n",
22     letters.lastIndexOf( 'a', 25 ) );
23 System.out.printf( "Last '$' is located at index %d\n\n",
24     letters.lastIndexOf( '$' ) );
25
26 // test indexOf to locate a substring in a string
27 System.out.printf( "\"def\" is located at index %d\n",
28     letters.indexOf( "def" ) );
29 System.out.printf( "\"def\" is located at index %d\n",
30     letters.indexOf( "def", 7 ) );
31 System.out.printf( "\"hello\" is located at index %d\n\n",
32     letters.indexOf( "hello" ) );
33
34 // test lastIndexOf to find a substring in a string
35 System.out.printf( "Last \"def\" is located at index %d\n",
36     letters.lastIndexOf( "def" ) );
37 System.out.printf( "Last \"def\" is located at index %d\n",
38     letters.lastIndexOf( "def", 25 ) );
39 System.out.printf( "Last \"hello\" is located at index %d\n",
40     letters.lastIndexOf( "hello" ) );
41 } // end main
42 } // end class StringIndexMethods

```

```

'c' is located at index 2
'a' is located at index 13
'$' is located at index -1

Last 'c' is located at index 15
Last 'a' is located at index 13
Last '$' is located at index -1

"def" is located at index 3
"def" is located at index 16
"hello" is located at index -1

Last "def" is located at index 16
Last "def" is located at index 16
Last "hello" is located at index -1

```

**Fig. 16.5** | String-searching methods `indexOf` and `lastIndexOf`. (Part 2 of 2.)

All the searches in this example are performed on the String `letters` (initialized with "abcdefghijklmabcdehijklm"). Lines 11–16 use method `indexOf` to locate the first

occurrence of a character in a `String`. If the method finds the character, it returns the character's index in the `String`—otherwise, it returns `-1`. There are two versions of `indexOf` that search for characters in a `String`. The expression in line 12 uses the version of method `indexOf` that takes an integer representation of the character to find. The expression at line 14 uses another version of method `indexOf`, which takes two integer arguments—the character and the starting index at which the search of the `String` should begin.

Lines 19–24 use method `lastIndexOf` to locate the last occurrence of a character in a `String`. The method searches from the end of the `String` toward the beginning. If it finds the character, it returns the character's index in the `String`—otherwise, it returns `-1`. There are two versions of `lastIndexOf` that search for characters in a `String`. The expression at line 20 uses the version that takes the integer representation of the character. The expression at line 22 uses the version that takes two integer arguments—the integer representation of the character and the index from which to begin searching backward.

Lines 27–40 demonstrate versions of methods `indexOf` and `lastIndexOf` that each take a `String` as the first argument. These versions perform identically to those described earlier except that they search for sequences of characters (or substrings) that are specified by their `String` arguments. If the substring is found, these methods return the index in the `String` of the first character in the substring.

### 16.3.5 Extracting Substrings from Strings

Class `String` provides two substring methods to enable a new `String` object to be created by copying part of an existing `String` object. Each method returns a new `String` object. Both methods are demonstrated in Fig. 16.6.

```

1 // Fig. 16.6: SubString.java
2 // String class substring methods.
3
4 public class SubString
5 {
6     public static void main( String[] args )
7     {
8         String letters = "abcdefghijklmabcdefghijklm";
9
10        // test substring methods
11        System.out.printf( "Substring from index 20 to end is \"%s\"\n",
12            letters.substring( 20 ) );
13        System.out.printf( "%s \"%s\"\n",
14            "Substring from index 3 up to, but not including 6 is",
15            letters.substring( 3, 6 ) );
16    } // end main
17 } // end class SubString

```

```

Substring from index 20 to end is "hijklm"
Substring from index 3 up to, but not including 6 is "def"

```

**Fig. 16.6** | String class substring methods.

The expression `letters.substring(20)` at line 12 uses the substring method that takes one integer argument. The argument specifies the starting index in the original

String letters from which characters are to be copied. The substring returned contains a copy of the characters from the starting index to the end of the String. Specifying an index outside the bounds of the String causes a **StringIndexOutOfBoundsException**.

Line 15 uses the substring method that takes two integer arguments—the starting index from which to copy characters in the original String and the index one beyond the last character to copy (i.e., copy up to, but not including, that index in the String). The substring returned contains a copy of the specified characters from the original String. An index outside the bounds of the String causes a **StringIndexOutOfBoundsException**.

### 16.3.6 Concatenating Strings

String method **concat** (Fig. 16.7) concatenates two String objects and returns a new String object containing the characters from both original Strings. The expression `s1.concat( s2 )` at line 13 forms a String by appending the characters in `s2` to the characters in `s1`. The original Strings to which `s1` and `s2` refer are not modified.

```

1 // Fig. 16.7: StringConcatenation.java
2 // String method concat.
3
4 public class StringConcatenation
5 {
6     public static void main( String[] args )
7     {
8         String s1 = "Happy ";
9         String s2 = "Birthday";
10
11         System.out.printf( "s1 = %s\ns2 = %s\n\n", s1, s2 );
12         System.out.printf(
13             "Result of s1.concat( s2 ) = %s\n", s1.concat( s2 ) );
14         System.out.printf( "s1 after concatenation = %s\n", s1 );
15     } // end main
16 } // end class StringConcatenation

```

```

s1 = Happy
s2 = Birthday

```

```

Result of s1.concat( s2 ) = Happy Birthday
s1 after concatenation = Happy

```

**Fig. 16.7** | String method `concat`.

### 16.3.7 Miscellaneous String Methods

Class String provides several methods that return modified copies of Strings or that return character arrays. These methods are demonstrated in the application in Fig. 16.8.

Line 16 uses String method `replace` to return a new String object in which every occurrence in `s1` of character 'l' (lowercase el) is replaced with character 'L'. Method `replace` leaves the original String unchanged. If there are no occurrences of the first argument in the String, method `replace` returns the original String. An overloaded version of method `replace` enables you to replace substrings rather than individual characters.

```

1 // Fig. 16.8: StringMiscellaneous2.java
2 // String methods replace, toLowerCase, toUpperCase, trim and toCharArray.
3
4 public class StringMiscellaneous2
5 {
6     public static void main( String[] args )
7     {
8         String s1 = "hello";
9         String s2 = "GOODBYE";
10        String s3 = "  spaces  ";
11
12        System.out.printf( "s1 = %s\ns2 = %s\ns3 = %s\n\n", s1, s2, s3 );
13
14        // test method replace
15        System.out.printf(
16            "Replace 'l' with 'L' in s1: %s\n\n", s1.replace( 'l', 'L' ) );
17
18        // test toLowerCase and toUpperCase
19        System.out.printf( "s1.toUpperCase() = %s\n", s1.toUpperCase() );
20        System.out.printf( "s2.toLowerCase() = %s\n\n", s2.toLowerCase() );
21
22        // test trim method
23        System.out.printf( "s3 after trim = \"%s\"\n\n", s3.trim() );
24
25        // test toCharArray method
26        char[] charArray = s1.toCharArray();
27        System.out.print( "s1 as a character array = " );
28
29        for ( char character : charArray )
30            System.out.print( character );
31
32        System.out.println();
33    } // end main
34 } // end class StringMiscellaneous2

```

```

s1 = hello
s2 = GOODBYE
s3 =  spaces

Replace 'l' with 'L' in s1: heLLo

s1.toUpperCase() = HELLO
s2.toLowerCase() = goodbye

s3 after trim = "spaces"

s1 as a character array = hello

```

**Fig. 16.8** | String methods `replace`, `toLowerCase`, `toUpperCase`, `trim` and `toCharArray`.

Line 19 uses String method **`toUpperCase`** to generate a new String with uppercase letters where corresponding lowercase letters exist in `s1`. The method returns a new String object containing the converted String and leaves the original String unchanged. If there are no characters to convert, method `toUpperCase` returns the original String.

Line 20 uses String method `toLowerCase` to return a new String object with lowercase letters where corresponding uppercase letters exist in `s2`. The original String remains unchanged. If there are no characters in the original String to convert, `toLowerCase` returns the original String.

Line 23 uses String method `trim` to generate a new String object that removes all white-space characters that appear at the beginning and/or end of the String on which `trim` operates. The method returns a new String object containing the String without leading or trailing white space. The original String remains unchanged. If there are no whitespace characters at the beginning and/or end, `trim` returns the original String.

Line 26 uses String method `toCharArray` to create a new character array containing a copy of the characters in `s1`. Lines 29–30 output each char in the array.

### 16.3.8 String Method `valueOf`

As we've seen, every object in Java has a `toString` method that enables a program to obtain the object's string representation. Unfortunately, this technique cannot be used with primitive types because they do not have methods. Class String provides static methods that take an argument of any type and convert it to a String object. Figure 16.9 demonstrates the String class `valueOf` methods.

The expression `String.valueOf(charArray)` at line 18 uses the character array `charArray` to create a new String object. The expression `String.valueOf(charArray, 3, 3)` at line 20 uses a portion of the character array `charArray` to create a new String object. The second argument specifies the starting index from which the characters are used. The third argument specifies the number of characters to be used.

---

```

1 // Fig. 16.9: StringValueOf.java
2 // String valueOf methods.
3
4 public class StringValueOf
5 {
6     public static void main( String[] args )
7     {
8         char[] charArray = { 'a', 'b', 'c', 'd', 'e', 'f' };
9         boolean booleanValue = true;
10        char characterValue = 'Z';
11        int integerValue = 7;
12        long longValue = 10000000000L; // L suffix indicates long
13        float floatValue = 2.5f; // f indicates that 2.5 is a float
14        double doubleValue = 33.333; // no suffix, double is default
15        Object objectRef = "hello"; // assign string to an Object reference
16
17        System.out.printf(
18            "char array = %s\n", String.valueOf( charArray ) );
19        System.out.printf( "part of char array = %s\n",
20            String.valueOf( charArray, 3, 3 ) );
21        System.out.printf(
22            "boolean = %s\n", String.valueOf( booleanValue ) );
23        System.out.printf(
24            "char = %s\n", String.valueOf( characterValue ) );

```

---

**Fig. 16.9** | String `valueOf` methods. (Part 1 of 2.)

```

25     System.out.printf( "int = %s\n", String.valueOf( integerValue ) );
26     System.out.printf( "long = %s\n", String.valueOf( longValue ) );
27     System.out.printf( "float = %s\n", String.valueOf( floatValue ) );
28     System.out.printf(
29         "double = %s\n", String.valueOf( doubleValue ) );
30     System.out.printf( "Object = %s", String.valueOf( objectRef ) );
31 } // end main
32 } // end class StringValueOf

```

```

char array = abcdef
part of char array = def
boolean = true
char = Z
int = 7
long = 10000000000L
float = 2.5f
double = 33.333
Object = hello

```

**Fig. 16.9** | String `valueOf` methods. (Part 2 of 2.)

There are seven other versions of method `valueOf`, which take arguments of type `boolean`, `char`, `int`, `long`, `float`, `double` and `Object`, respectively. These are demonstrated in lines 21–30. The version of `valueOf` that takes an `Object` as an argument can do so because all `Objects` can be converted to `Strings` with method `toString`.

[*Note:* Lines 12–13 use literal values `10000000000L` and `2.5f` as the initial values of `long` variable `longValue` and `float` variable `floatValue`, respectively. By default, Java treats integer literals as type `int` and floating-point literals as type `double`. Appending the letter `L` to the literal `10000000000` and appending letter `f` to the literal `2.5` indicates to the compiler that `10000000000` should be treated as a `long` and `2.5` as a `float`. An uppercase `L` or lowercase `l` can be used to denote a variable of type `long` and an uppercase `F` or lowercase `f` can be used to denote a variable of type `float`.]

## 16.4 Class `StringBuilder`

We now discuss the features of class `StringBuilder` for creating and manipulating *dynamic* string information—that is, *modifiable* strings. Every `StringBuilder` is capable of storing a number of characters specified by its capacity. If a `StringBuilder`'s capacity is exceeded, the capacity expands to accommodate the additional characters.

### Performance Tip 16.2

Java can perform certain optimizations involving `String` objects (such as referring to one `String` object from multiple variables) because it knows these objects will not change. `Strings` (not `StringBuilders`) should be used if the data will not change.

### Performance Tip 16.3

In programs that frequently perform string concatenation, or other string modifications, it's often more efficient to implement the modifications with class `StringBuilder`.

### Software Engineering Observation 16.2

*StringBuilders are not thread safe. If multiple threads require access to the same dynamic string information, use class **StringBuffer** in your code. Classes `StringBuilder` and `StringBuffer` provide identical capabilities, but class `StringBuffer` is thread safe. For more details on threading, see Chapter 26.*

## 16.4.1 StringBuilder Constructors

Class `StringBuilder` provides four constructors. We demonstrate three of these in Fig. 16.10. Line 8 uses the no-argument `StringBuilder` constructor to create a `StringBuilder` with no characters in it and an initial capacity of 16 characters (the default for a `StringBuilder`). Line 9 uses the `StringBuilder` constructor that takes an integer argument to create a `StringBuilder` with no characters in it and the initial capacity specified by the integer argument (i.e., 10). Line 10 uses the `StringBuilder` constructor that takes a `String` argument to create a `StringBuilder` containing the characters in the `String` argument. The initial capacity is the number of characters in the `String` argument plus 16.

Lines 12–14 implicitly use the method `toString` of class `StringBuilder` to output the `StringBuilder`s with the `printf` method. In Section 16.4.4, we discuss how Java uses `StringBuilder` objects to implement the `+` and `+=` operators for string concatenation.

```

1 // Fig. 16.10: StringBuilderConstructors.java
2 // StringBuilder constructors.
3
4 public class StringBuilderConstructors
5 {
6     public static void main( String[] args )
7     {
8         StringBuilder buffer1 = new StringBuilder();
9         StringBuilder buffer2 = new StringBuilder( 10 );
10        StringBuilder buffer3 = new StringBuilder( "hello" );
11
12        System.out.printf( "buffer1 = \"%s\"\n", buffer1 );
13        System.out.printf( "buffer2 = \"%s\"\n", buffer2 );
14        System.out.printf( "buffer3 = \"%s\"\n", buffer3 );
15    } // end main
16 } // end class StringBuilderConstructors

```

```

buffer1 = ""
buffer2 = ""
buffer3 = "hello"

```

**Fig. 16.10** | `StringBuilder` constructors.

## 16.4.2 StringBuilder Methods `length`, `capacity`, `setLength` and `ensureCapacity`

Class `StringBuilder` provides methods **length** and **capacity** to return the number of characters currently in a `StringBuilder` and the number of characters that can be stored in a `StringBuilder` without allocating more memory, respectively. Method **ensureCapacity** guarantees that a `StringBuilder` has at least the specified capacity. Method

setLength increases or decreases the length of a StringBuilder. Figure 16.11 demonstrates these methods.

```

1 // Fig. 16.11: StringBuilderCapLen.java
2 // StringBuilder length, setLength, capacity and ensureCapacity methods.
3
4 public class StringBuilderCapLen
5 {
6     public static void main( String[] args )
7     {
8         StringBuilder buffer = new StringBuilder( "Hello, how are you?" );
9
10        System.out.printf( "buffer = %s\nlength = %d\ncapacity = %d\n\n",
11            buffer.toString(), buffer.length(), buffer.capacity() );
12
13        buffer.ensureCapacity( 75 );
14        System.out.printf( "New capacity = %d\n\n", buffer.capacity() );
15
16        buffer.setLength( 10 );
17        System.out.printf( "New length = %d\nbuffer = %s\n",
18            buffer.length(), buffer.toString() );
19    } // end main
20 } // end class StringBuilderCapLen

```

```

buffer = Hello, how are you?
length = 19
capacity = 35

New capacity = 75

New length = 10
buffer = Hello, how

```

**Fig. 16.11** | StringBuilder length, setLength, capacity and ensureCapacity methods.

The application contains one `StringBuilder` called `buffer`. Line 8 uses the `StringBuilder` constructor that takes a `String` argument to initialize the `StringBuilder` with "Hello, how are you?". Lines 10–11 print the contents, length and capacity of the `StringBuilder`. Note in the output window that the capacity of the `StringBuilder` is initially 35. Recall that the `StringBuilder` constructor that takes a `String` argument initializes the capacity to the length of the string passed as an argument plus 16.

Line 13 uses method `ensureCapacity` to expand the capacity of the `StringBuilder` to a minimum of 75 characters. Actually, if the original capacity is less than the argument, the method ensures a capacity that's the greater of the number specified as an argument and twice the original capacity plus 2. The `StringBuilder`'s current capacity remains unchanged if it's more than the specified capacity.

#### Performance Tip 16.4

*Dynamically increasing the capacity of a `StringBuilder` can take a relatively long time. Executing a large number of these operations can degrade the performance of an application. If a `StringBuilder` is going to increase greatly in size, possibly multiple times, setting its capacity high at the beginning will increase performance.*

Line 16 uses method `setLength` to set the length of the `StringBuilder` to 10. If the specified length is less than the current number of characters in the `StringBuilder`, the buffer is truncated to the specified length (i.e., the characters in the `StringBuilder` after the specified length are discarded). If the specified length is greater than the number of characters currently in the `StringBuilder`, null characters (characters with the numeric representation 0) are appended until the total number of characters in the `StringBuilder` is equal to the specified length.

### 16.4.3 `StringBuilder` Methods `charAt`, `setCharAt`, `getChars` and `reverse`

Class `StringBuilder` provides methods `charAt`, `setCharAt`, `getChars` and `reverse` to manipulate the characters in a `StringBuilder` (Fig. 16.12). Method `charAt` (line 12) takes an integer argument and returns the character in the `StringBuilder` at that index. Method `getChars` (line 15) copies characters from a `StringBuilder` into the character array passed as an argument. This method takes four arguments—the starting index from which characters should be copied in the `StringBuilder`, the index one past the last character to be copied from the `StringBuilder`, the character array into which the characters are to be copied and the starting location in the character array where the first character should be placed. Method `setCharAt` (lines 21 and 22) takes an integer and a character argument and sets the character at the specified position in the `StringBuilder` to the character argument. Method `reverse` (line 25) reverses the contents of the `StringBuilder`.

#### Common Programming Error 16.3

*Attempting to access a character that's outside the bounds of a `StringBuilder` (i.e., with an index less than 0 or greater than or equal to the `StringBuilder`'s length) results in a `StringIndexOutOfBoundsException`.*

```

1 // Fig. 16.12: StringBuilderChars.java
2 // StringBuilder methods charAt, setCharAt, getChars and reverse.
3
4 public class StringBuilderChars
5 {
6     public static void main( String[] args )
7     {
8         StringBuilder buffer = new StringBuilder( "hello there" );
9
10        System.out.printf( "buffer = %s\n", buffer.toString() );
11        System.out.printf( "Character at 0: %s\nCharacter at 4: %s\n\n",
12                          buffer.charAt( 0 ), buffer.charAt( 4 ) );
13
14        char[] charArray = new char[ buffer.length() ];
15        buffer.getChars( 0, buffer.length(), charArray, 0 );
16        System.out.print( "The characters are: " );
17
18        for ( char character : charArray )
19            System.out.print( character );

```

```

20
21     buffer.setCharAt( 0, 'H' );
22     buffer.setCharAt( 6, 'T' );
23     System.out.printf( "\n\nbuffer = %s", buffer.toString() );
24
25     buffer.reverse();
26     System.out.printf( "\n\nbuffer = %s\n", buffer.toString() );
27 } // end main
28 } // end class StringBuilderChars

```

```

buffer = hello there
Character at 0: h
Character at 4: o

The characters are: hello there

buffer = Hello There

buffer = erehT olleH

```

**Fig. 16.12** | StringBuilder methods charAt, setCharAt, getChars and reverse. (Part 2 of 2.)

#### 16.4.4 StringBuilder append Methods

Class `StringBuilder` provides overloaded **append** methods (Fig. 16.13) to allow values of various types to be appended to the end of a `StringBuilder`. Versions are provided for each of the primitive types, and for character arrays, Strings, Objects, and more. (Remember that method `toString` produces a string representation of any Object.) Each method takes its argument, converts it to a string and appends it to the `StringBuilder`.

```

1 // Fig. 16.13: StringBuilderAppend.java
2 // StringBuilder append methods.
3
4 public class StringBuilderAppend
5 {
6     public static void main( String[] args )
7     {
8         Object objectRef = "hello";
9         String string = "goodbye";
10        char[] charArray = { 'a', 'b', 'c', 'd', 'e', 'f' };
11        boolean booleanValue = true;
12        char characterValue = 'Z';
13        int integerValue = 7;
14        long longValue = 10000000000L;
15        float floatValue = 2.5f;
16        double doubleValue = 33.333;
17
18        StringBuilder lastBuffer = new StringBuilder( "last buffer" );
19        StringBuilder buffer = new StringBuilder();
20
21        buffer.append( objectRef );

```

**Fig. 16.13** | StringBuilder append methods. (Part 1 of 2.)

```

22     buffer.append( "\n" );
23     buffer.append( string );
24     buffer.append( "\n" );
25     buffer.append( charArray );
26     buffer.append( "\n" );
27     buffer.append( charArray, 0, 3 );
28     buffer.append( "\n" );
29     buffer.append( booleanValue );
30     buffer.append( "\n" );
31     buffer.append( characterValue );
32     buffer.append( "\n" );
33     buffer.append( integerValue );
34     buffer.append( "\n" );
35     buffer.append( longValue );
36     buffer.append( "\n" );
37     buffer.append( floatValue );
38     buffer.append( "\n" );
39     buffer.append( doubleValue );
40     buffer.append( "\n" );
41     buffer.append( lastBuffer );
42
43     System.out.printf( "buffer contains %s\n", buffer.toString() );
44 } // end main
45 } // end StringBuilderAppend

```

```

buffer contains hello
goodbye
abcdef
abc
true
Z
7
10000000000
2.5
33.333
last buffer

```

**Fig. 16.13** | StringBuilder append methods. (Part 2 of 2.)

Actually, a compiler can use `StringBuilder` (or `StringBuffer`) and the `append` methods to implement the `+` and `+=` String concatenation operators. For example, assuming the declarations

```

String string1 = "hello";
String string2 = "BC";
int value = 22;

```

the statement

```
String s = string1 + string2 + value;
```

concatenates "hello", "BC" and 22. The concatenation can be performed as follows:

```
String s = new StringBuilder().append( "hello" ).append( "BC" ).
append( 22 ).toString();
```

First, the preceding statement creates an empty `StringBuilder`, then appends to it the strings "hello" and "BC" and the integer 22. Next, `StringBuilder`'s `toString` method converts the `StringBuilder` to a `String` object to be assigned to `String s`. The statement

```
s += "!";
```

can be performed as follows (this may differ by compiler):

```
s = new StringBuilder().append( s ).append( "!" ).toString();
```

This creates an empty `StringBuilder`, then appends to it the current contents of `s` followed by "!". Next, `StringBuilder`'s method `toString` (which must be called explicitly here) returns the `StringBuilder`'s contents as a `String`, and the result is assigned to `s`.

### 16.4.5 StringBuilder Insertion and Deletion Methods

`StringBuilder` provides overloaded **insert** methods to insert values of various types at any position in a `StringBuilder`. Versions are provided for the primitive types and for character arrays, `Strings`, `Objects` and `CharSequences`. Each method takes its second argument and inserts it at the index specified by the first argument. If the first argument is less than 0 or greater than the `StringBuilder`'s length, a `StringIndexOutOfBoundsException` occurs. Class `StringBuilder` also provides methods **delete** and **deleteCharAt** to delete characters at any position in a `StringBuilder`. Method `delete` takes two arguments—the starting index and the index one past the end of the characters to delete. All characters beginning at the starting index up to but not including the ending index are deleted. Method `deleteCharAt` takes one argument—the index of the character to delete. Invalid indices cause both methods to throw a `StringIndexOutOfBoundsException`. Figure 16.14 demonstrates methods `insert`, `delete` and `deleteCharAt`.

---

```

1 // Fig. 16.14: StringBuilderInsertDelete.java
2 // StringBuilder methods insert, delete and deleteCharAt.
3
4 public class StringBuilderInsertDelete
5 {
6     public static void main( String[] args )
7     {
8         Object objectRef = "hello";
9         String string = "goodbye";
10        char[] charArray = { 'a', 'b', 'c', 'd', 'e', 'f' };
11        boolean booleanValue = true;
12        char characterValue = 'K';
13        int integerValue = 7;
14        long longValue = 10000000;
15        float floatValue = 2.5f; // f suffix indicates that 2.5 is a float
16        double doubleValue = 33.333;
17
18        StringBuilder buffer = new StringBuilder();
19
20        buffer.insert( 0, objectRef );
21        buffer.insert( 0, " " ); // each of these contains two spaces
22        buffer.insert( 0, string );

```

**Fig. 16.14** | `StringBuilder` methods `insert`, `delete` and `deleteCharAt`. (Part 1 of 2.)

```

23     buffer.insert( 0, " " );
24     buffer.insert( 0, charArray );
25     buffer.insert( 0, " " );
26     buffer.insert( 0, charArray, 3, 3 );
27     buffer.insert( 0, " " );
28     buffer.insert( 0, booleanValue );
29     buffer.insert( 0, " " );
30     buffer.insert( 0, characterValue );
31     buffer.insert( 0, " " );
32     buffer.insert( 0, integerValue );
33     buffer.insert( 0, " " );
34     buffer.insert( 0, longValue );
35     buffer.insert( 0, " " );
36     buffer.insert( 0, floatValue );
37     buffer.insert( 0, " " );
38     buffer.insert( 0, doubleValue );
39
40     System.out.printf(
41         "buffer after inserts:\n%s\n\n", buffer.toString() );
42
43     buffer.deleteCharAt( 10 ); // delete 5 in 2.5
44     buffer.delete( 2, 6 ); // delete .333 in 33.333
45
46     System.out.printf(
47         "buffer after deletes:\n%s\n", buffer.toString() );
48     } // end main
49 } // end class StringBuilderInsertDelete

```

```

buffer after inserts:
33.333 2.5 10000000 7 K true def abcdef goodbye hello

buffer after deletes:
33 2. 10000000 7 K true def abcdef goodbye hello

```

## 16.5 Class Character

Java provides eight type-wrapper classes—Boolean, Character, Double, Float, Byte, Short, Integer and Long—that enable primitive-type values to be treated as objects. In this section, we present class Character—the type-wrapper class for primitive type char.

Most Character methods are static methods designed for convenience in processing individual char values. These methods take at least a character argument and perform either a test or a manipulation of the character. Class Character also contains a constructor that receives a char argument to initialize a Character object. Most of the methods of class Character are presented in the next three examples. For more information on class Character (and all the type-wrapper classes), see the `java.lang` package in the Java API documentation.

Figure 16.15 demonstrates static methods that test characters to determine whether they're a specific character type and the static methods that perform case conversions on characters. You can enter any character and apply the methods to the character.

Line 15 uses Character method **isDefined** to determine whether character *c* is defined in the Unicode character set. If so, the method returns true; otherwise, it returns false. Line 16 uses Character method **isDigit** to determine whether character *c* is a defined Unicode digit. If so, the method returns true, and otherwise, false.

```

1 // Fig. 16.15: StaticCharMethods.java
2 // Character static methods for testing characters and converting case.
3 import java.util.Scanner;
4
5 public class StaticCharMethods
6 {
7     public static void main( String[] args )
8     {
9         Scanner scanner = new Scanner( System.in ); // create scanner
10        System.out.println( "Enter a character and press Enter" );
11        String input = scanner.next();
12        char c = input.charAt( 0 ); // get input character
13
14        // display character info
15        System.out.printf( "is defined: %b\n", Character.isDefined( c ) );
16        System.out.printf( "is digit: %b\n", Character.isDigit( c ) );
17        System.out.printf( "is first character in a Java identifier: %b\n",
18            Character.isJavaIdentifierStart( c ) );
19        System.out.printf( "is part of a Java identifier: %b\n",
20            Character.isJavaIdentifierPart( c ) );
21        System.out.printf( "is letter: %b\n", Character.isLetter( c ) );
22        System.out.printf(
23            "is letter or digit: %b\n", Character.isLetterOrDigit( c ) );
24        System.out.printf(
25            "is lower case: %b\n", Character.isLowerCase( c ) );
26        System.out.printf(
27            "is upper case: %b\n", Character.isUpperCase( c ) );
28        System.out.printf(
29            "to upper case: %s\n", Character.toUpperCase( c ) );
30        System.out.printf(
31            "to lower case: %s\n", Character.toLowerCase( c ) );
32    } // end main
33 } // end class StaticCharMethods

```

```

Enter a character and press Enter
A
is defined: true
is digit: false
is first character in a Java identifier: true

is letter or digit: true
is lower case: false
is upper case: false
to upper case: 8
to lower case: 8

```

```

Enter a character and press Enter
$
is defined: true
is digit: false
is first character in a Java identifier: true
is part of a Java identifier: true
is letter: false
is letter or digit: false
is lower case: false
is upper case: false
to upper case: $
to lower case: $

```

**Fig. 16.15** | Character static methods for testing characters and converting case. (Part 2 of 2.)

Line 18 uses Character method **isJavaIdentifierStart** to determine whether *c* is a character that can be the first character of an identifier in Java—that is, a letter, an underscore (`_`) or a dollar sign (`$`). If so, the method returns `true`, and otherwise, `false`. Line 20 uses Character method **isJavaIdentifierPart** to determine whether character *c* is a character that can be used in an identifier in Java—that is, a digit, a letter, an underscore (`_`) or a dollar sign (`$`). If so, the method returns `true`, and otherwise, `false`.

Line 21 uses Character method **isLetter** to determine whether character *c* is a letter. If so, the method returns `true`, and otherwise, `false`. Line 23 uses Character method **isLetterOrDigit** to determine whether character *c* is a letter or a digit. If so, the method returns `true`, and otherwise, `false`.

Line 25 uses Character method **isLowerCase** to determine whether character *c* is a lowercase letter. If so, the method returns `true`, and otherwise, `false`. Line 27 uses Character method **isUpperCase** to determine whether character *c* is an uppercase letter. If so, the method returns `true`, and otherwise, `false`.

Line 29 uses Character method **toUpperCase** to convert the character *c* to its uppercase equivalent. The method returns the converted character if the character has an uppercase equivalent, and otherwise, the method returns its original argument. Line 31 uses Character method **toLowerCase** to convert the character *c* to its lowercase equivalent. The method returns the converted character if the character has a lowercase equivalent, and otherwise, the method returns its original argument.

Figure 16.16 demonstrates static Character methods **digit** and **forDigit**, which convert characters to digits and digits to characters, respectively, in different number sys-

tems. Common number systems include decimal (base 10), octal (base 8), hexadecimal (base 16) and binary (base 2). The base of a number is also known as its **radix**. For more information on conversions between number systems, see Appendix H.

Line 28 uses method `forDigit` to convert the integer `digit` into a character in the number system specified by the integer `radix` (the base of the number). For example, the decimal integer 13 in base 16 (the `radix`) has the character value 'd'. Lowercase and uppercase letters represent the same value in number systems. Line 35 uses method `digit` to convert variable `character` into an integer in the number system specified by the integer `radix` (the base of the number). For example, the character 'A' is the base 16 (the `radix`) representation of the base 10 value 10. The `radix` must be between 2 and 36, inclusive.

---

```

1 // Fig. 16.16: StaticCharMethods2.java
2 // Character class static conversion methods.
3 import java.util.Scanner;
4
5 public class StaticCharMethods2
6 {
7     // executes application
8     public static void main( String[] args )
9     {
10         Scanner scanner = new Scanner( System.in );
11
12         // get radix
13         System.out.println( "Please enter a radix:" );
14         int radix = scanner.nextInt();
15
16         // get user choice
17         System.out.printf( "Please choose one:\n1 -- %s\n2 -- %s\n",
18             "Convert digit to character", "Convert character to digit" );
19         int choice = scanner.nextInt();
20
21         // process request
22         switch ( choice )
23         {
24             case 1: // convert digit to character
25                 System.out.println( "Enter a digit:" );
26                 int digit = scanner.nextInt();
27                 System.out.printf( "Convert digit to character: %s\n",
28                     Character.forDigit( digit, radix ) );
29                 break;
30
31             case 2: // convert character to digit
32                 System.out.println( "Enter a character:" );
33                 char character = scanner.next().charAt( 0 );
34                 System.out.printf( "Convert character to digit: %s\n",
35                     Character.digit( character, radix ) );
36                 break;
37         } // end switch
38     } // end main
39 } // end class StaticCharMethods2

```

---

**Fig. 16.16** | Character class static conversion methods. (Part 2 of 2.)

Figure 16.17 demonstrates the constructor and several non-static methods of class `Character`—`charValue`, `toString` and `equals`. Lines 7–8 instantiate two `Character` objects by assigning the character constants 'A' and 'a', respectively, to the `Character` variables. Java automatically converts these `char` literals into `Character` objects—a process known as *autoboxing* that we discuss in more detail in Section 20.4. Line 11 uses `Character` method `charValue` to return the `char` value stored in `Character` object `c1`. Line 11 returns a string representation of `Character` object `c2` using method `toString`. The condition in line 13 uses method `equals` to determine whether the object `c1` has the same contents as the object `c2` (i.e., the characters inside each object are equal).

```

1 // Fig. 16.17: OtherCharMethods.java
2 // Character class non-static methods.
3 public class OtherCharMethods
4 {
5     public static void main( String[] args )
6     {
7         Character c1 = 'A';
8         Character c2 = 'a';
9
10        System.out.printf(
11            "c1 = %s\nc2 = %s\n", c1.charValue(), c2.toString() );
12
13        if ( c1.equals( c2 ) )
14            System.out.println( "c1 and c2 are equal\n" );
15        else
16            System.out.println( "c1 and c2 are not equal\n" );
17    } // end main
18 } // end class OtherCharMethods

```

## 16.6 Tokenizing Strings

When you read a sentence, your mind breaks it into **tokens**—individual words and punctuation marks that convey meaning to you. Compilers also perform tokenization. They break up statements into individual pieces like keywords, identifiers, operators and other programming-language elements. We now study class `String`'s **`split`** method, which breaks a `String` into its component tokens. Tokens are separated from one another by **delimiters**, typically white-space characters such as space, tab, newline and carriage return. Other characters can also be used as delimiters to separate tokens. The application in Fig. 16.18 demonstrates `String`'s `split` method.

When the user presses the *Enter* key, the input sentence is stored in variable `sentence`. Line 17 invokes `String` method `split` with the `String` argument " ", which returns an array of `Strings`. The space character in the argument `String` is the delimiter that method `split` uses to locate the tokens in the `String`. As you'll learn in the next section, the argument to method `split` can be a regular expression for more complex tokenizing. Line 19 displays the length of the array `tokens`—i.e., the number of tokens in `sentence`. Lines 21–22 output each token on a separate line.

```
1 // Fig. 16.18: TokenTest.java
2 // StringTokenizer object used to tokenize strings.
3 import java.util.Scanner;
4 import java.util.StringTokenizer;
5
6 public class TokenTest
7 {
8     // execute application
9     public static void main( String[] args )
10    {
11        // get sentence
12        Scanner scanner = new Scanner( System.in );
13        System.out.println( "Enter a sentence and press Enter" );
14        String sentence = scanner.nextLine();
15
16        // process user sentence
17        String[] tokens = sentence.split( " " );
18        System.out.printf( "Number of elements: %d\nThe tokens are:\n",
19                          tokens.length );
20
21        for ( String token : tokens )
22            System.out.println( token );
23    } // end main
24 } // end class TokenTest
```

The tokens are:
This
is
a
sentence
with
seven
tokens

```

**Fig. 16.18** | StringTokenizer object used to tokenize strings. (Part 2 of 2.)

## 16.7 Regular Expressions, Class Pattern and Class Matcher

A **regular expression** is a `String` that describes a search pattern for matching characters in other `Strings`. Such expressions are useful for validating input and ensuring that data is in a particular format. For example, a ZIP code must consist of five digits, and a last name must contain only letters, spaces, apostrophes and hyphens. One application of regular expressions is to facilitate the construction of a compiler. Often, a large and complex regular expression is used to validate the syntax of a program. If the program code does not match the regular expression, the compiler knows that there's a syntax error in the code.

Class `String` provides several methods for performing regular-expression operations, the simplest of which is the matching operation. `String` method **`matches`** receives a `String` that specifies the regular expression and matches the contents of the `String` object on which it's called to the regular expression. The method returns a `boolean` indicating whether the match succeeded.

A regular expression consists of literal characters and special symbols. Figure 16.19 specifies some **predefined character classes** that can be used with regular expressions. A character class is an escape sequence that represents a group of characters. A digit is any numeric character. A **word character** is any letter (uppercase or lowercase), any digit or the underscore character. A white-space character is a space, a tab, a carriage return, a newline or a form feed. Each character class matches a single character in the `String` we're attempting to match with the regular expression.

Regular expressions are not limited to these predefined character classes. The expressions employ various operators and other forms of notation to match complex patterns.

| Character       | Matches                   | Character       | Matches                      |
|-----------------|---------------------------|-----------------|------------------------------|
| <code>\d</code> | any digit                 | <code>\D</code> | any nondigit                 |
| <code>\w</code> | any word character        | <code>\W</code> | any nonword character        |
| <code>\s</code> | any white-space character | <code>\S</code> | any nonwhite-space character |

**Fig. 16.19** | Predefined character classes.

We examine several of these techniques in the application in Figs. 16.20 and 16.21, which validates user input via regular expressions. [*Note:* This application is not designed to match all possible valid user input.]

---

```

1 // Fig. 16.20: ValidateInput.java

**Fig. 16.21** | Inputs and validates data from user using the `ValidateInput` class. (Part 2 of 2.)

Figure 16.20 validates user input. Line 9 validates the first name. To match a set of characters that does not have a predefined character class, use square brackets, `[]`. For example, the pattern `"[aeiou]"` matches a single character that's a vowel. Character ranges are represented by placing a dash (`-`) between two characters. In the example, `"[A-Z]"` matches a single uppercase letter. If the first character in the brackets is `"^"`, the expression accepts any character other than those indicated. However, `"[^Z]"` is not the same as `"[A-Y]"`, which matches uppercase letters A–Y—`"[^Z]"` matches any character other than capital Z, including lowercase letters and nonletters such as the newline character. Ranges in character classes are determined by the letters' integer values. In this example, `"[A-Za-z]"` matches all uppercase and lowercase letters. The range `"[A-z]"` matches all letters and also matches those characters (such as `[` and `\`) with an integer value between uppercase Z and lowercase a (for more information on integer values of characters see Appendix B). Like predefined character classes, character classes delimited by square brackets match a single character in the search object.

In line 9, the asterisk after the second character class indicates that any number of letters can be matched. In general, when the regular-expression operator `"*"` appears in a regular expression, the application attempts to match zero or more occurrences of the subexpression immediately preceding the `"*"`. Operator `"+"` attempts to match one or

more occurrences of the subexpression immediately preceding "+". So both "A\*" and "A+" will match "AAA" or "A", but only "A\*" will match an empty string.

If method `validateFirstName` returns `true` (line 29 of Fig. 16.21), the application attempts to validate the last name (line 31) by calling `validateLastName` (lines 13–16 of Fig. 16.20). The regular expression to validate the last name matches any number of letters split by spaces, apostrophes or hyphens.

Line 33 of Fig. 16.21 calls method `validateAddress` (lines 19–23 of Fig. 16.20) to validate the address. The first character class matches any digit one or more times (`\\d+`). Two `\\` characters are used, because `\\` normally starts an escape sequence in a string. So `\\d` in a `String` represents the regular expression pattern `\\d`. Then we match one or more white-space characters (`\\s+`). The character `|` matches the expression to its left or to its right. For example, `"Hi (John|Jane)"` matches both `"Hi John"` and `"Hi Jane"`. The parentheses are used to group parts of the regular expression. In this example, the left side of `|` matches a single word, and the right side matches two words separated by any amount of white space. So the address must contain a number followed by one or two words. Therefore, `"10 Broadway"` and `"10 Main Street"` are both valid addresses in this example. The city (lines 26–29 of Fig. 16.20) and state (lines 32–35 of Fig. 16.20) methods also match any word of at least one character or, alternatively, any two words of at least one character if the words are separated by a single space, so both `Wal``tham` and `West` `Newton` would match.

### Quantifiers

The asterisk (`*`) and plus (`+`) are formally called **quantifiers**. Figure 16.22 lists all the quantifiers. We've already discussed how the asterisk (`*`) and plus (`+`) quantifiers work. All quantifiers affect only the subexpression immediately preceding the quantifier. Quantifier question mark (`?`) matches zero or one occurrences of the expression that it quantifies. A set of braces containing one number (`{n}`) matches exactly  $n$  occurrences of the expression it quantifies. We demonstrate this quantifier to validate the zip code in Fig. 16.20 at line 40. Including a comma after the number enclosed in braces matches at least  $n$  occurrences of the quantified expression. The set of braces containing two numbers (`{n,m}`), matches between  $n$  and  $m$  occurrences of the expression that it qualifies. Quantifiers may be applied to patterns enclosed in parentheses to create more complex regular expressions.

| Quantifier         | Matches                                              |
|--------------------|------------------------------------------------------|
| <code>*</code>     | Matches zero or more occurrences of the pattern.     |
| <code>+</code>     | Matches one or more occurrences of the pattern.      |
| <code>?</code>     | Matches zero or one occurrences of the pattern.      |
| <code>{n}</code>   | Matches exactly $n$ occurrences.                     |
| <code>{n,}</code>  | Matches at least $n$ occurrences.                    |
| <code>{n,m}</code> | Matches between $n$ and $m$ (inclusive) occurrences. |

**Fig. 16.22** | Quantifiers used in regular expressions.

All of the quantifiers are **greedy**. This means that they'll match as many occurrences as they can as long as the match is still successful. However, if any of these quantifiers is

followed by a question mark (?), the quantifier becomes **reluctant** (sometimes called **lazy**). It then will match as few occurrences as possible as long as the match is still successful.

The zip code (line 40 in Fig. 16.20) matches a digit five times. This regular expression uses the digit character class and a quantifier with the digit 5 between braces. The phone number (line 46 in Fig. 16.20) matches three digits (the first one cannot be zero) followed by a dash followed by three more digits (again the first one cannot be zero) followed by four more digits.

String method `matches` checks whether an entire String conforms to a regular expression. For example, we want to accept "Smith" as a last name, but not "9@Smith#". If only a substring matches the regular expression, method `matches` returns false.

### *Replacing Substrings and Splitting Strings*

Sometimes it's useful to replace parts of a string or to split a string into pieces. For this purpose, class String provides methods **`replaceAll`**, **`replaceFirst`** and **`split`**. These methods are demonstrated in Fig. 16.23.

---

```

1 // Fig. 16.23: RegexSubstitution.java
2 // String methods replaceFirst, replaceAll and split.
3 import java.util.Arrays;
4
5 public class RegexSubstitution
6 {
7     public static void main( String[] args )
8     {
9         String firstString = "This sentence ends in 5 stars *****";
10        String secondString = "1, 2, 3, 4, 5, 6, 7, 8";
11
12        System.out.printf( "Original String 1: %s\n", firstString );
13
14        // replace '*' with '^'
15        firstString = firstString.replaceAll( "\\*", "^" );
16
17        System.out.printf( "^ substituted for *: %s\n", firstString );
18
19        // replace 'stars' with 'carets'
20        firstString = firstString.replaceAll( "stars", "carets" );
21
22        System.out.printf(
23            "\"carets\" substituted for \"stars\": %s\n", firstString );
24
25        // replace words with 'word'
26        System.out.printf( "Every word replaced by \"word\": %s\n\n",
27            firstString.replaceAll( "\\w+", "word" ) );
28
29        System.out.printf( "Original String 2: %s\n", secondString );
30
31        // replace first three digits with 'digit'
32        for ( int i = 0; i < 3; i++ )
33            secondString = secondString.replaceFirst( "\\d", "digit" );
34

```

---

**Fig. 16.23** | String methods `replaceFirst`, `replaceAll` and `split`. (Part I of 2.)

```

35     System.out.printf(
36         "First 3 digits replaced by \"digit\" : %s\n", secondString );
37
38     System.out.print( "String split at commas: " );
39     String[] results = secondString.split( ",\\s*" ); // split on commas
40     System.out.println( Arrays.toString( results ) );
41 } // end main
42 } // end class RegexSubstitution

```

```

Original String 1: This sentence ends in 5 stars *****
^ substituted for *: This sentence ends in 5 stars ^^^^^
"carets" substituted for "stars": This sentence ends in 5 carets ^^^^^
Every word replaced by "word": word word word word word word ^^^^^

Original String 2: 1, 2, 3, 4, 5, 6, 7, 8
First 3 digits replaced by "digit" : digit, digit, digit, 4, 5, 6, 7, 8
String split at commas: ["digit", "digit", "digit", "4", "5", "6", "7", "8"]

```

**Fig. 16.23** | String methods `replaceFirst`, `replaceAll` and `split`. (Part 2 of 2.)

Method `replaceAll` replaces text in a `String` with new text (the second argument) wherever the original `String` matches a regular expression (the first argument). Line 15 replaces every instance of "\*" in `firstString` with "^". The regular expression ("\\s\*") precedes character \* with two backslashes. Normally, \* is a quantifier indicating that a regular expression should match any number of occurrences of a preceding pattern. However, in line 15, we want to find all occurrences of the literal character \*—to do this, we must escape character \* with character \. Escaping a special regular-expression character with \ instructs the matching engine to find the actual character. Since the expression is stored in a Java `String` and \ is a special character in Java `Strings`, we must include an additional \. So the Java `String` "\\s\*" represents the regular-expression pattern \\* which matches a single \* character in the search string. In line 20, every match for the regular expression "stars" in `firstString` is replaced with "carets". Line 27 uses `replaceAll` to replace all words in the string with "word".

Method `replaceFirst` (line 33) replaces the first occurrence of a pattern match. Java `Strings` are immutable; therefore, method `replaceFirst` returns a new `String` in which the appropriate characters have been replaced. This line takes the original `String` and replaces it with the `String` returned by `replaceFirst`. By iterating three times we replace the first three instances of a digit (\d) in `secondString` with the text "digit".

Method `split` divides a `String` into several substrings. The original is broken in any location that matches a specified regular expression. Method `split` returns an array of `Strings` containing the substrings between matches for the regular expression. In line 39, we use method `split` to tokenize a `String` of comma-separated integers. The argument is the regular expression that locates the delimiter. In this case, we use the regular expression ",\\s\*" to separate the substrings wherever a comma occurs. By matching any white-space characters, we eliminate extra spaces from the resulting substrings. The commas and white-space characters are not returned as part of the substrings. Again, the Java `String` ",\\s\*" represents the regular expression ,\s\*. Line 40 uses `Arrays` method `toString` to display the contents of array `results` in square brackets and separated by commas.

### Classes Pattern and Matcher

In addition to the regular-expression capabilities of class `String`, Java provides other classes in package `java.util.regex` that help developers manipulate regular expressions. Class **Pattern** represents a regular expression. Class **Matcher** contains both a regular-expression pattern and a `CharSequence` in which to search for the pattern.

**CharSequence** (package `java.lang`) is an interface that allows read access to a sequence of characters. The interface requires that the methods `charAt`, `length`, `subSequence` and `toString` be declared. Both `String` and `StringBuilder` implement interface `CharSequence`, so an instance of either of these classes can be used with class `Matcher`.

#### Common Programming Error 16.4

*A regular expression can be tested against an object of any class that implements interface `CharSequence`, but the regular expression must be a `String`. Attempting to create a regular expression as a `StringBuilder` is an error.*

If a regular expression will be used only once, static `Pattern` method `matches` can be used. This method takes a `String` that specifies the regular expression and a `CharSequence` on which to perform the match. This method returns a `boolean` indicating whether the search object (the second argument) matches the regular expression.

If a regular expression will be used more than once (in a loop, for example), it's more efficient to use static `Pattern` method `compile` to create a specific `Pattern` object for that regular expression. This method receives a `String` representing the pattern and returns a new `Pattern` object, which can then be used to call method `matcher`. This method receives a `CharSequence` to search and returns a `Matcher` object.

`Matcher` provides method `matches`, which performs the same task as `Pattern` method `matches`, but receives no arguments—the search pattern and search object are encapsulated in the `Matcher` object. Class `Matcher` provides other methods, including `find`, `lookingAt`, `replaceFirst` and `replaceAll`.

Figure 16.24 presents a simple example that employs regular expressions. This program matches birthdays against a regular expression. The expression matches only birthdays that do not occur in April and that belong to people whose names begin with "J".

Lines 11–12 create a `Pattern` by invoking static `Pattern` method `compile`. The dot character "." in the regular expression (line 12) matches any single character except a new-line character.

```

1 // Fig. 16.24: RegexMatches.java
2 // Classes Pattern and Matcher.
3 import java.util.regex.Matcher;
4 import java.util.regex.Pattern;
5
6 public class RegexMatches
7 {
8     public static void main( String[] args )
9     {
10         // create regular expression
11         Pattern expression =
12             Pattern.compile( "J.*\\d[0-35-9]-\\d\\d-\\d\\d" );

```

**Fig. 16.24** | Classes Pattern and Matcher. (Part I of 2.)

```

13
14     String string1 = "Jane's Birthday is 05-12-75\n" +
15         "Dave's Birthday is 11-04-68\n" +
16         "John's Birthday is 04-28-73\n" +
17         "Joe's Birthday is 12-17-77";
18
19     // match regular expression to string and print matches
20     Matcher matcher = expression.matcher( string1 );
21
22     while ( matcher.find() )
23         System.out.println( matcher.group() );
24 } // end main
25 } // end class RegexMatches

```

```

Jane's Birthday is 05-12-75
Joe's Birthday is 12-17-77

```

**Fig. 16.24** | Classes Pattern and Matcher. (Part 2 of 2.)

Line 20 creates the `Matcher` object for the compiled regular expression and the matching sequence (`string1`). Lines 22–23 use a `while` loop to iterate through the `String`. Line 22 uses `Matcher` method `find` to attempt to match a piece of the search object to the search pattern. Each call to this method starts at the point where the last call ended, so multiple matches can be found. `Matcher` method `lookingAt` performs the same way, except that it always starts from the beginning of the search object and will always find the first match if there is one.

### Common Programming Error 16.5

*Method `matches` (from class `String`, `Pattern` or `Matcher`) will return `true` only if the entire search object matches the regular expression. Methods `find` and `lookingAt` (from class `Matcher`) will return `true` if a portion of the search object matches the regular expression.*

Line 23 uses `Matcher` method `group`, which returns the `String` from the search object that matches the search pattern. The `String` that's returned is the one that was last matched by a call to `find` or `lookingAt`. The output in Fig. 16.24 shows the two matches that were found in `string1`.

For more information on regular expressions, visit our Regular Expressions Resource Center at [www.deitel.com/regexexpressions/](http://www.deitel.com/regexexpressions/).

## 16.8 Wrap-Up

In this chapter, you learned about more `String` methods for selecting portions of `Strings` and manipulating `Strings`. You learned about the `Character` class and some of the methods it declares to handle chars. The chapter also discussed the capabilities of the `StringBuilder` class for creating `Strings`. The end of the chapter discussed regular expressions, which provide a powerful capability to search and match portions of `Strings` that fit a particular pattern. In the next chapter, you'll learn about file processing, including how persistent data is stored and retrieved.

## Summary

### Section 16.2 Fundamentals of Characters and Strings

- A character literal's value (p. 673) is its integer value in Unicode (p. 673). Strings can include letters, digits and special characters such as +, -, \*, / and \$. A string in Java is an object of class `String`. String literals (p. 674) are often referred to as `String` objects and are written in a program in double quotes.

### Section 16.3 Class `String`

- `String` objects are immutable (p. 675)—after they're created, their character contents cannot be changed.
- `String` method `length` (p. 675) returns the number of characters in a `String`.
- `String` method `charAt` (p. 675) returns the character at a specific position.
- `String` method `equals` tests for equality. The method returns `true` if the contents of the `Strings` are equal, `false` otherwise. Method `equals` uses a lexicographical comparison (p. 679) for `Strings`.
- When primitive-type values are compared with `==`, the result is `true` if both values are identical. When references are compared with `==`, the result is `true` if both refer to the same object.
- Java treats all string literals with the same contents as a single `String` object.
- `String` method `equalsIgnoreCase` performs a case-insensitive string comparison.
- `String` method `compareTo` uses a lexicographical comparison and returns 0 if the `Strings` are equal, a negative number if the string that calls `compareTo` is less than the argument `String` and a positive number if the string that calls `compareTo` is greater than than the argument `String`.
- `String` method `regionMatches` (p. 677) compares portions of two strings for equality.
- `String` methods `startsWith` and `endsWith` (p. 680) determine whether a string starts with or ends with the specified characters, respectively.
- `String` method `indexOf` (p. 681) locates the first occurrence of a character or a substring in a string. `String` method `lastIndexOf` (p. 681) locates the last occurrence of a character or a substring in a string.
- `String` method `substring` copies and returns part of an existing string object.
- `String` method `concat` concatenates two string objects and returns a new string object.
- `String` method `replace` returns a new string object that replaces every occurrence in a `String` of its first character argument with its second character argument.
- `String` method `toUpperCase` (p. 685) returns a new string with uppercase letters in the positions where the original string had lowercase letters. `String` method `toLowerCase` (p. 686) returns a new string with lowercase letters in the positions where the original string had uppercase letters.
- `String` method `trim` (p. 686) returns a new string object in which all white-space characters (e.g., spaces, newlines and tabs) have been removed from the beginning and end of a string.
- `String` method `toCharArray` (p. 686) returns a `char` array containing a copy of the string's characters.
- `String` class static method `valueOf` returns its argument converted to a string.

### Section 16.4 Class `StringBuilder`

- Class `StringBuilder` provides constructors that enable `StringBuilders` to be initialized with no characters and an initial capacity of 16 characters, with no characters and an initial capacity specified in the integer argument, or with a copy of the characters of the `String` argument and an initial capacity that's the number of characters in the `String` argument plus 16.

- `StringBuilder` method `length` (p. 688) returns the number of characters currently stored in a `StringBuilder`. `StringBuilder` method `capacity` (p. 688) returns the number of characters that can be stored in a `StringBuilder` without allocating more memory.
- `StringBuilder` method `ensureCapacity` (p. 688) ensures that a `StringBuilder` has at least the specified capacity. Method `setLength` increases or decreases the length of a `StringBuilder`.
- `StringBuilder` method `charAt` (p. 690) returns the character at the specified index. Method `setCharAt` (p. 690) sets the character at the specified position. `StringBuilder` method `getChars` (p. 690) copies characters in the `StringBuilder` into the character array passed as an argument.
- `StringBuilder`'s overloaded `append` methods (p. 691) add primitive-type, character array, `String`, `Object` or `CharSequence` (p. 707) values to the end of a `StringBuilder`.
- `StringBuilder`'s overloaded `insert` (p. 693) methods insert primitive-type, character array, `String`, `Object` or `CharSequence` values at any position in a `StringBuilder`.

### Section 16.5 Class `Character`

- `Character` method `isDefined` (p. 695) determines whether a character is in the Unicode character set.
- `Character` method `isDigit` (p. 695) determines whether a character is a defined Unicode digit.
- `Character` method `isJavaIdentifierStart` (p. 696) determines whether a character can be used as the first character of a Java identifier. `Character` method `isJavaIdentifierPart` (p. 696) determines if a character can be used in an identifier.
- `Character` method `isLetter` (p. 696) determines if a character is a letter. `Character` method `isLetterOrDigit` (p. 696) determines if a character is a letter or a digit.
- `Character` method `isLowerCase` (p. 696) determines whether a character is a lowercase letter. `Character` method `isUpperCase` (p. 696) determines whether a character is an uppercase letter.
- `Character` method `toUpperCase` (p. 696) converts a character to its uppercase equivalent. `Character` method `toLowerCase` (p. 696) converts a character to its lowercase equivalent.
- `Character` method `digit` (p. 696) converts its character argument into an integer in the number system specified by its integer argument `radix` (p. 697). `Character` method `forDigit` (p. 696) converts its integer argument `digit` into a character in the number system specified by its integer argument `radix`.
- `Character` method `charValue` (p. 698) returns the char stored in a `Character` object. `Character` method `toString` returns a `String` representation of a `Character`.

### Section 16.6 Tokenizing Strings

- Class `String`'s `split` method (p. 705) tokenizes a `String` based on the delimiter (p. 699) specified as an argument and returns an array of `Strings` containing the tokens (p. 699).

### Section 16.7 Regular Expressions, Class `Pattern` and Class `Matcher`

- Regular expressions (p. 700) are sequences of characters and symbols that define a set of strings. They're useful for validating input and ensuring that data is in a particular format.
- `String` method `matches` (p. 700) receives a string that specifies the regular expression and matches the contents of the `String` object on which it's called to the regular expression. The method returns a `boolean` indicating whether the match succeeded.
- A character class is an escape sequence that represents a group of characters. Each character class matches a single character in the string we're attempting to match with the regular expression.
- A word character (`\w`; p. 700) is any letter (uppercase or lowercase), any digit or the underscore character.

- A white-space character (`\s`) is a space, a tab, a carriage return, a newline or a form feed.
- A digit (`\d`) is any numeric character.
- To match a set of characters that does not have a predefined character class (p. 700), use square brackets, `[]`. Ranges can be represented by placing a dash (`-`) between two characters. If the first character in the brackets is `^`, the expression accepts any character other than those indicated.
- When the regular expression operator `*` appears in a regular expression, the program attempts to match zero or more occurrences of the subexpression immediately preceding the `*`.
- Operator `+` attempts to match one or more occurrences of the subexpression preceding it.
- The character `|` allows a match of the expression to its left or to its right.
- Parentheses `()` are used to group parts of the regular expression.
- The asterisk (`*`) and plus (`+`) are formally called quantifiers (p. 704).
- A quantifier affects only the subexpression immediately preceding it.
- Quantifier question mark (`?`) matches zero or one occurrences of the expression that it quantifies.
- A set of braces containing one number (`{n}`) matches exactly  $n$  occurrences of the expression it quantifies. Including a comma after the number enclosed in braces matches at least  $n$  occurrences.
- A set of braces containing two numbers (`{n,m}`) matches between  $n$  and  $m$  occurrences of the expression that it qualifies.
- Quantifiers are greedy (p. 704)—they'll match as many occurrences as they can as long as the match is successful. If a quantifier is followed by a question mark (`?`), the quantifier becomes reluctant (p. 705), matching as few occurrences as possible as long as the match is successful.
- String method `replaceAll` (p. 705) replaces text in a string with new text (the second argument) wherever the original string matches a regular expression (the first argument).
- Escaping a special regular-expression character with a `\` instructs the regular-expression matching engine to find the actual character, as opposed to what it represents in a regular expression.
- String method `replaceFirst` (p. 705) replaces the first occurrence of a pattern match and returns a new string in which the appropriate characters have been replaced.
- String method `split` divides a string into substrings at any location that matches a specified regular expression and returns an array of the substrings.
- Class `Pattern` (p. 707) represents a regular expression.
- Class `Matcher` (p. 707) contains a regular-expression pattern and a `CharSequence` in which to search.
- `CharSequence` is an interface (p. 707) that allows read access to a sequence of characters. Both `String` and `StringBuilder` implement this interface, so they can be used with class `Matcher`.
- If a regular expression will be used only once, static `Pattern` method `matches` (p. 707) takes a string that specifies the regular expression and a `CharSequence` on which to perform the match. This method returns a `boolean` indicating whether the search object matches the regular expression.
- If a regular expression will be used more than once, it's more efficient to use static `Pattern` method `compile` (p. 707) to create a specific `Pattern` object for that regular expression. This method receives a string representing the pattern and returns a new `Pattern` object.
- `Pattern` method `matcher` (p. 707) receives a `CharSequence` to search and returns a `Matcher` object. `Matcher` method `matches` (p. 707) performs the same task as `Pattern` method `matches` but without arguments.
- `Matcher` method `find` (p. 707) attempts to match a piece of the search object to the search pattern. Each call to this method starts at the point where the last call ended, so multiple matches can be found.

- Matcher method `lookingAt` (p. 707) performs the same as `find`, except that it always starts from the beginning of the search object and will always find the first match if there is one.
- Matcher method `group` (p. 708) returns the string from the search object that matches the search pattern. The string returned is the one that was last matched by a call to `find` or `lookingAt`.

## Self-Review Exercises

- 16.1** State whether each of the following is *true* or *false*. If *false*, explain why.
- When `String` objects are compared using `==`, the result is *true* if the `Strings` contain the same values.
  - A `String` can be modified after it's created.
- 16.2** For each of the following, write a single statement that performs the indicated task:
- Compare the string in `s1` to the string in `s2` for equality of contents.
  - Append the string `s2` to the string `s1`, using `+=`.
  - Determine the length of the string in `s1`.

## Answers to Self-Review Exercises

- 16.1**
- False*. `String` objects are compared using operator `==` to determine whether they're the same object in memory.
  - False*. `String` objects are immutable and cannot be modified after they're created. `StringBuilder` objects can be modified after they're created.
- 16.2**
- `s1.equals( s2 )`
  - `s1 += s2;`
  - `s1.length()`

## Exercises

**16.3** (*Comparing Strings*) Write an application that uses `String` method `compareTo` to compare two strings input by the user. Output whether the first string is less than, equal to or greater than the second.

**16.4** (*Comparing Portions of Strings*) Write an application that uses `String` method `regionMatches` to compare two strings input by the user. The application should input the number of characters to be compared and the starting index of the comparison. The application should state whether the strings are equal. Ignore the case of the characters when performing the comparison.

**16.5** (*Random Sentences*) Write an application that uses random-number generation to create sentences. Use four arrays of strings called `article`, `noun`, `verb` and `preposition`. Create a sentence by selecting a word at random from each array in the following order: `article`, `noun`, `verb`, `preposition`, `article` and `noun`. As each word is picked, concatenate it to the previous words in the sentence. The words should be separated by spaces. When the final sentence is output, it should start with a capital letter and end with a period. The application should generate and display 20 sentences.

The `article` array should contain the articles "the", "a", "one", "some" and "any"; the `noun` array should contain the nouns "boy", "girl", "dog", "town" and "car"; the `verb` array should contain the verbs "drove", "jumped", "ran", "walked" and "skipped"; the `preposition` array should contain the prepositions "to", "from", "over", "under" and "on".

**16.6** (*Project: Limericks*) A limerick is a humorous five-line verse in which the first and second lines rhyme with the fifth, and the third line rhymes with the fourth. Using techniques similar to those developed in Exercise 16.5, write a Java application that produces random limericks. Polishing this application to produce good limericks is a challenging problem, but the result will be worth the effort!

**16.7** (*Pig Latin*) Write an application that encodes English-language phrases into pig Latin. Pig Latin is a form of coded language. There are many different ways to form pig Latin phrases. For simplicity, use the following algorithm:

To form a pig Latin phrase from an English-language phrase, tokenize the phrase into words with `String` method `split`. To translate each English word into a pig Latin word, place the first letter of the English word at the end of the word and add the letters “ay.” Thus, the word “jump” becomes “umpjay,” the word “the” becomes “hetay,” and the word “computer” becomes “omputer-cay.” Blanks between words remain as blanks. Assume the following: The English phrase consists of words separated by blanks, there are no punctuation marks and all words have two or more letters. Method `printLatinWord` should display each word. Each token is passed to method `printLatinWord` to print the pig Latin word. Enable the user to input the sentence. Keep a running display of all the converted sentences in a text area.

**16.8** (*Tokenizing Telephone Numbers*) Write an application that inputs a telephone number as a string in the form (555) 555-5555. The application should use `String` method `split` to extract the area code as a token, the first three digits of the phone number as a token and the last four digits of the phone number as a token. The seven digits of the phone number should be concatenated into one string. Both the area code and the phone number should be printed. Remember that you’ll have to change delimiter characters during the tokenization process.

**16.9** (*Displaying a Sentence with Its Words Reversed*) Write an application that inputs a line of text, tokenizes the line with `String` method `split` and outputs the tokens in reverse order. Use space characters as delimiters.

**16.10** (*Displaying Strings in Uppercase and Lowercase*) Write an application that inputs a line of text and outputs the text twice—once in all uppercase letters and once in all lowercase letters.

**16.11** (*Searching Strings*) Write an application that inputs a line of text and a search character and uses `String` method `indexOf` to determine the number of occurrences of the character in the text.

**16.12** (*Searching Strings*) Write an application based on the application in Exercise 16.11 that inputs a line of text and uses `String` method `indexOf` to determine the total number of occurrences of each letter of the alphabet in the text. Uppercase and lowercase letters should be counted together. Store the totals for each letter in an array, and print the values in tabular format after the totals have been determined.

**16.13** (*Tokenizing and Comparing Strings*) Write an application that reads a line of text, tokenizes the line using space characters as delimiters and outputs only those words beginning with the letter “b”.

**16.14** (*Tokenizing and Comparing Strings*) Write an application that reads a line of text, tokenizes it using space characters as delimiters and outputs only those words ending with the letters “ED”.

**16.15** (*Converting int Values to Characters*) Write an application that inputs an integer code for a character and displays the corresponding character. Modify this application so that it generates all possible three-digit codes in the range from 000 to 255 and attempts to print the corresponding characters.

**16.16** (*Defining Your Own String Methods*) Write your own versions of `String` search methods `indexOf` and `lastIndexOf`.

**16.17** (*Creating Three-Letter Strings from a Five-Letter Word*) Write an application that reads a five-letter word from the user and produces every possible three-letter string that can be derived from the letters of that word. For example, the three-letter words produced from the word “bathe” include “ate,” “bat,” “bet,” “tab,” “hat,” “the” and “tea.”

## Special Section: Advanced String-Manipulation Exercises

The preceding exercises are keyed to the text and designed to test your understanding of fundamental string-manipulation concepts. This section includes a collection of intermediate and advanced string-manipulation exercises. You should find these problems challenging, yet entertaining. The problems vary considerably in difficulty. Some require an hour or two of application writing and implementation. Others are useful for lab assignments that might require two or three weeks of study and implementation. Some are challenging term projects.

**16.18 (Text Analysis)** The availability of computers with string-manipulation capabilities has resulted in some rather interesting approaches to analyzing the writings of great authors. Much attention has been focused on whether William Shakespeare ever lived. Some scholars believe there's substantial evidence indicating that Christopher Marlowe actually penned the masterpieces attributed to Shakespeare. Researchers have used computers to find similarities in the writings of these two authors. This exercise examines three methods for analyzing texts with a computer.

- a) Write an application that reads a line of text from the keyboard and prints a table indicating the number of occurrences of each letter of the alphabet in the text. For example, the phrase

To be, or not to be: that is the question:

contains one "a," two "b's," no "c's," and so on.

- b) Write an application that reads a line of text and prints a table indicating the number of one-letter words, two-letter words, three-letter words, and so on, appearing in the text. For example, Fig. 16.25 shows the counts for the phrase

Whether 'tis nobler in the mind to suffer

| Word length | Occurrences        |
|-------------|--------------------|
| 1           | 0                  |
| 2           | 2                  |
| 3           | 1                  |
| 4           | 2 (including 'tis) |
| 5           | 0                  |
| 6           | 2                  |
| 7           | 1                  |

**Fig. 16.25** | Word-length counts for the string "Whether 'tis nobler in the mind to suffer".

- c) Write an application that reads a line of text and prints a table indicating the number of occurrences of each different word in the text. The application should include the words in the table in the same order in which they appear in the text. For example, the lines

To be, or not to be: that is the question:  
Whether 'tis nobler in the mind to suffer

contain the word "to" three times, the word "be" two times, the word "or" once, etc.

**16.19 (Printing Dates in Various Formats)** Dates are printed in several common formats. Two of the more common formats are

04/25/1955 and April 25, 1955

Write an application that reads a date in the first format and prints it in the second format.

**16.20 (Check Protection)** Computers are frequently employed in check-writing systems, such as payroll and accounts payable applications. There are many strange stories about weekly paychecks being printed (by mistake) for amounts in excess of \$1 million. Incorrect amounts are printed by computerized check-writing systems because of human error or machine failure. Systems designers build controls into their systems to prevent such erroneous checks from being issued.

Another serious problem is the intentional alteration of a check amount by someone who plans to cash a check fraudulently. To prevent a dollar amount from being altered, some computerized check-writing systems employ a technique called check protection. Checks designed for imprinting by computer contain a fixed number of spaces in which the computer may print an amount. Suppose a paycheck contains eight blank spaces in which the computer is supposed to print the amount of a weekly paycheck. If the amount is large, then all eight of the spaces will be filled. For example,

```
1,230.60 (check amount)
-----
12345678 (position numbers)
```

On the other hand, if the amount is less than \$1000, then several of the spaces would ordinarily be left blank. For example,

```
99.87
-----
12345678
```

contains three blank spaces. If a check is printed with blank spaces, it's easier for someone to alter the amount. To prevent alteration, many check-writing systems insert *leading asterisks* to protect the amount as follows:

```
***99.87
-----
12345678
```

Write an application that inputs a dollar amount to be printed on a check, then prints the amount in check-protected format with leading asterisks if necessary. Assume that nine spaces are available for printing the amount.

**16.21 (Writing the Word Equivalent of a Check Amount)** Continuing the discussion in Exercise 16.20, we reiterate the importance of designing check-writing systems to prevent alteration of check amounts. One common security method requires that the amount be written in numbers and spelled out in words as well. Even if someone is able to alter the numerical amount of the check, it's extremely difficult to change the amount in words. Write an application that inputs a numeric check amount that's less than \$1000 and writes the word equivalent of the amount. For example, the amount 112.43 should be written as

```
ONE hundred TWELVE and 43/100
```

**16.22 (Morse Code)** Perhaps the most famous of all coding schemes is the Morse code, developed by Samuel Morse in 1832 for use with the telegraph system. The Morse code assigns a series of dots and dashes to each letter of the alphabet, each digit, and a few special characters (e.g., period, comma, colon, semicolon). In sound-oriented systems, the dot represents a short sound and the dash a long sound. Other representations of dots and dashes are used with light-oriented systems and signal-flag systems. Separation between words is indicated by a space or, simply, the absence of a dot or dash. In a sound-oriented system, a space is indicated by a short time during which no sound is transmitted. The international version of the Morse code appears in Fig. 16.26.

Write an application that reads an English-language phrase and encodes it into Morse code. Also write an application that reads a phrase in Morse code and converts it into the English-language equivalent. Use one blank between each Morse-coded letter and three blanks between each Morse-coded word.

| Character | Code    | Character | Code    | Character     | Code      |
|-----------|---------|-----------|---------|---------------|-----------|
| A         | .-      | N         | -.      | <i>Digits</i> |           |
| B         | ....    | O         | ---     | 1             | ....-     |
| C         | -. .    | P         | .- .    | 2             | ..- -     |
| D         | - . .   | Q         | - . -   | 3             | ... -     |
| E         | .       | R         | . - .   | 4             | .... -    |
| F         | .. - .  | S         | ... .   | 5             | .....     |
| G         | - - .   | T         | -       | 6             | - . . . . |
| H         | ....    | U         | . . -   | 7             | - - . . . |
| I         | ..      | V         | ... -   | 8             | - - - . . |
